ABSTRACT
We present a microfluidic cell-trap that utilizes negative dielectrophoresis (nDEP) force and hydrodynamic force generated by a pillar array capable of controlling the number of trapped particles accurately. By adjusting the relative strength of the nDEP and hydrodynamic forces, the trap located at the region close to the stagnation point of pillar functions as both a single-particle trap (capable of discriminating particles based on size or material properties) and a multi-particle trap (capable of controlling the number of particles trapped). We used 5\textmu m PS beads to validate and demonstrate the capability of this new cell-trap design. Pulsed nDEP is used to increase the selectivity and stability. Good correlation between simulation and the experiment results was obtained.

KEYWORDS: Cell-Trap, Dielectrophoresis, Pillar array.

INTRODUCTION
Trapping of single particle in microfluidic devices is very important due to its potential application in single cell analysis. DEP provides a simple and inexpensive way for trapping and manipulating particles by varying the voltage, frequency or phase of the electrical signal applied to the electrodes in such devices. So far, a few research groups have demonstrated the ability to trap a single particle in their devices [1] [2]. However, there are still some drawbacks, such as the ignorance of the particle-particle interaction and the complicated fabrication. In our present work, we developed a novel device in which a pulsed nDEP force, instead of continuous nDEP, is used to achieve a stable single/multi-particle trap.

THEORY AND SIMULATION
Figure 1 shows a schematic drawing of a representative section in a pillar array structure. The actual array consists of a 20 by 30 grid fabricated in a microchip.

For a spherical particle with radius \( r \) suspended in a medium, the DEP force is given by,
\[
F_{\text{DEP}} = 2\pi \varepsilon_0 E_{\text{rms}}^3 \text{Re}[K^* (\omega)] \nabla E_{\text{rms}}^2
\]
where \( E_{\text{rms}} \) is the root mean square of electrical field strength. The direction of DEP depends on the sign of \( \text{Re}(K^* (\omega)) \). Countered by the hydrodynamic force, the sphere reaches a terminal velocity \( U_p \) given by,
\[
U_p = \frac{F_{\text{DEP}}}{6\pi \mu} + U_f
\]
where \( \mu \) is the viscosity of fluid, and \( U_f \) the fluid velocity. In this work, a commercial finite element software (COMSOL, Inc.) is used to analyse the steady state electric field and fluid flow field. The region where particles will be trapped is given by that where the X-component of the particle velocity is less than zero (as given by Eq. 2). The region is highlighted by the black contour in Figure 2.

**Figure 1.** Top view (left panel) and side view (right panel) of the pillar array. The pillar has diameter of 45\( \mu \)m and height of 30 \( \mu \)m. The distance between the centers of two pillars is 70\( \mu \)m. Both the width of electrodes and the gap between are 30 \( \mu \)m. The diameter of beads used is 5 \( \mu \)m. The vertical component of nDEP pushes the beads to top surface and the horizon component of nDEP pushes the beads back to the stagnation point behind the pillar. By adjusting the relative strength of the DEP and hydrodynamic forces, a controllable trap is realized. Pulsing the DEP force makes the trap more stable.

**EXPERIMENTAL METHOD**

ITO coated glass was used because of its high transparency and good electrical conductivity. Standard photolithography is used to pattern the interdigital electrodes (IDEs). Two SU-8 layers were then fabricated: one for pillar array and is the other for the rectangular channel. PS beads were mixed with water and a little surfactant is added to reduce the non-specific adhesion. A 10 MHz sinusoidal voltage up to 20Vpp
generated by signal generator is applied to the electrodes. The built-in amplitude modulating function of the signal generator is also used to produce the pulsed DEP.

Figure 3. Fluorescent image of experimental result under pulsed nDEP to trap single 5 µm bead in the pillar array. Blue circles show the position of the SU-8 pillars which are actually invisible under the fluorescent microscope. Small light dots represent the trapped fluorescent 5 µm beads. Fluid flows from top to bottom.

RESULTS AND DISCUSSION

Table 1 shows the number of particles trapped when continuous nDEP was applied, for various combinations of voltage and fluid flow velocity. When pulsed nDEP is used, the trap was found to be more stable, and a large scale array of traps can be realized as shown in Figure 3. The pulsed nDEP helps to reduce the particle-particle interaction. The number of particles trapped in the experiments is close to that predicted by simulation. The discrepancy is probably due to the uncertainty of fabricated channel height. Also, near-wall stick-slip effects and lift-forces may affect the experimental observations.

CONCLUSIONS

A microfluidic cell-trap array was developed based on the interplay of two set of forces: fluid flow and nDEP. The number of beads trapped is controlled by the voltage and flow rate applied. Pulsing the nDEP force helps to eliminate the particle-particle interaction resulting in a more stable trap. Experimental results obtained with 5µm polystyrene beads are close to that predicted by a simulation model.
