Synthesis of polyethylene-\textit{b}-poly(\textit{tert}-butylacrylate) (PE-\textit{b}-PrBA) diblock copolymers

\textbf{Materials.} All manipulations involving air- and/or moisture-sensitive compounds were carried out in a glove box or by using Schlenk technique. Trimethylsulfoxonium iodide (Acros, 98\%), benzyltributylammonium chloride (Acros, 98+\%), Celite-545 (Acros), borane dimethyl sulfide (Acros, 1 M in CH\textsubscript{2}Cl\textsubscript{2}), phenolphthalein (Acros, 98.5\%), trimethylamine \textit{N}-oxide dehydrate (Acros, 98\%), and 2-bromo-2-methylpropionyl bromide (Acros, 98\%) and \textit{N},\textit{N},\textit{N}',\textit{N}'',\textit{N}'''-pentamethyldiethylenetriamine (PMDETA, Alfa, 98\%) were used as received without further purification. \textit{tert}-butylacrylate (\textit{t}-BuA, Alfa, 99\%) was washed with 5\% (w/v) aqueous NaOH solution and then washed with distilled water. After drying over calcium hydride and filtering off the drying agent, the monomer was distilled under vacuum. Copper (I) bromide (Acros, 99.9\%) was purified by washing with 3\% (v/v) aqueous glacial acetic acid solution, followed by ethanol and diethyl ether, and finally dried under vacuum overnight. Sodium hydride (NaH, Acros, 60\%, dispersed in mineral oil) was washed thrice with \textit{n}-hexane to remove mineral oil before use. Toluene and \textit{n}-hexane were refluxed over sodium flakes/benzophenone and distilled under N\textsubscript{2} before use. Pyridine was dried over NaOH for several days before use. Other chemicals were all used as received.

\textbf{Polymer characterization.} All \textsuperscript{1}H-NMR (300 MHz) spectra were recorded on a Varian Mercury plus spectrometer in 1,2-dichlorobenzene-\textit{d}_4 at 120 °C. GPC analyses of PE-OH and PE-\textit{b}-PrBA were performed on a Polymer Laboratories PL-220 instrument equipped with three PL-gel columns (PL-gel 10 \textmu m MIXED-B, 300×7.5 mm). The instrument was calibrated with polystyrene standards. The samples (3.0
mg/mL in 1,2,4-trichlorobenzene) were run using 1,2,4-trichlorobenzene as eluent with a flow rate of 1.0 mL/min at 150 °C.

**Preparation of hydroxyl terminated polyethylene.** Hydroxyl terminated polyethylene (PE-OH) was prepared through polyhomologation of dimethylsulfoxonium methylyde and the subsequent oxidation of trisorganoborane using trimethylamine-N-oxide dihydrate.¹

Dimethylsulfoxonium chloride: A biphasic mixture of CH₂Cl₂ (400 mL) and H₂O (570 mL) with trimethylsulfoxonium iodide (63.1 g, 287 mmol, 1.0 equiv.) and benzyltributylammonium chloride (98.5 g, 316 mmol, 1.1 equiv.) was vigorously stirred in a flask under darkness for 28 h. The aqueous phase was separated, washed with CH₂Cl₂ (3 × 60 mL), and evaporated under vacuum. The white solid was recrystallized in methanol/toluene (95/5 v/v) mixed solvent, then ground into fine powder, and dried in a vacuum at 50 °C for 24 h to yield a white powder product (36.6 g, 99.2% yield).

Dimethylsulfoxonium methylyde: Sodium hydride (60% dispersion in oil, 7.5 g, 186.6 mmol, 1.5 equiv.) was washed with hexane (3 × 50 mL) under nitrogen. Trace of solvent was removed under vacuum. Trimethylsulfoxonium chloride (16 g, 124.4 mmol, 1.0 equiv.) and toluene (150 mL) were transferred to the flask. The heterogeneous reaction mixture was heated to reflux until no H₂ was released (usually 2-4 h). The contents were cooled to room temperature and filtered under nitrogen through pre-dried Celite 545 to afford a colorless solution of ylide (0.76 M in toluene, 88.0% yield). The solution was stored at -20 °C. An aliquot of the solution (1.0 mL) was added to H₂O (5 mL) and titrated with standardized HCl solution before use.

α-Hydroxypolyethylene: BH₃·SMe₂ (1.0 M in CH₂Cl₂, 0.1 mL, 0.1 mmol) was added rapidly via syringe to a solution of ylide (0.68 M in toluene, 103.5 mL, 70.4
mmol) at room temperature under N\textsubscript{2} followed with heating to 90 °C. After 15 min, a drop of the reaction mixture was added to H\textsubscript{2}O (3 mL) containing phenolphthalein and if the aqueous solution did not turn into red then it can be confirmed that ylide had been consumed. The solution was cooled to room temperature, and trimethylamine-N-oxide dihydrate (70 mg, 70.6 mmol) was added to the flask under N\textsubscript{2}, then the solution was heated to 90 °C and held for 2 h. The solution was cooled to room temperature and precipitated with acetonitrile (200 mL). The precipitate was filtered and successively washed with CH\textsubscript{3}CN (20 mL), acetone (20 mL), and hexane (20 mL), and then dried to give a white solid (1.00 g, >99% yield).

**Preparation of PE-b-PrBA diblock copolymers.** The PE-macroinitiator was first prepared via esterification of end hydroxyl group in PE-OH with 2-bromo-2-methylpropionyl bromide.\textsuperscript{2} In a typical procedure, PE-OH (1 g; 0.364 mmol of -OH groups), toluene (100 mL), pyridine (0.35 mL, 4.36 mmol) and 2-bromo-2-methylpropionyl bromide (0.45 mL, 3.64 mmol) were successively added into a nitrogen-purged, round-bottom flask (250 mL) equipped with a stirring bar and a condenser. The mixture was stirred vigorously at 100 °C for 12 h, then cooled to room temperature and poured into 500 mL of acidic methanol (containing 30 mL of 1 M aqueous HCl). The resulting polymer was collected by filtration, and successively washed with methanol (30 mL, ×2), 1 M aqueous HCl solution (10 mL, ×2), methanol (20 mL, ×2), and finally dried at 50 °C overnight in vacuum to yield an off-white solid polymer.

PE-b-PrBA BCPs were prepared by atom transfer radical polymerization (ATRP) of tert-butylacrylate in toluene in the presence of PE-macroinitiator, which followed the procedure of Lu et al.\textsuperscript{2} In a typical procedure, PE-macroinitiator (0.3 g, 0.103 mmol), toluene (5 mL), PMDETA (52 µL, 0.248 mmol) and tBA monomer (1.5 mL,
10.3 mmol) were successively added into a nitrogen-purged, 25 mL Schlenk flask equipped with a stirring bar. After the PE-macroinitiator was completely dissolved at 80 °C, the flask was cooled to room temperature and deoxygenated by degassing and backfilling with nitrogen for thrice. Then, CuBr (18 mg, 0.124 mmol) was added into the flask under N₂. The polymerization was performed at 100 °C for 4 h. The polymerization was stopped via cooling with a liquid nitrogen bath. The reaction mixture was poured into a beaker with cold methanol (500 mL) and water (100 mL) under magnetic stirring. The diblock copolymer PE-b-PtBA was filtered, washed with methanol and water for several times, and then dried overnight at 40 °C under vacuum. The molecular weight of PE-b-PtBA was controlled via monomer feed ratio and polymerization time.

The synthesis route of PE-b-PtBA diblock polymers is illustrated in Scheme S1. Figure S1 shows the ¹H-NMR spectra of PE-OH, PE-macroinitiator and PE-b-PtBA. The integral ratio of peak d (−CH₂O−, δ = 3.60 ppm) to peak a (−CH₃, δ = 1.02 ppm) in PE-OH was 1/3, the ideal ratio should be 2/3 and this can be ascribed to the incorporation of dimethylsulfoxonium ethylide impurity in ylide which has already...
been mentioned in the literature.\textsuperscript{1} The absolute number-average molecular weight was calculated from the \textsuperscript{1}H-NMR spectrum (Figure S1(I)) using following equations below:

\begin{align*}
N_{\text{chain}} &= A_d/2 \quad \text{(S1)} \\
\text{DP} &= A_{\text{brc}}/4N_{\text{chain}} + 1 \quad \text{(S2)} \\
M_n &= \text{DP} \times 28 \, (\text{g/mol}) \quad \text{(S3)}
\end{align*}

Where \(N_{\text{chain}}\) represents the number of polyethylene blocks, DP is the degree of polymerization, \(M_n\) is the number-average molecular weight of PE calculated from \textsuperscript{1}H-NMR. The smaller values of polydispersity index (PDI) indicated that the living polymerization of sulfoxide ylide was well-controlled, as illustrated in Table S1 and Figure S2.

The \textsuperscript{1}H-NMR of macroinitiator PE-Br and PE-OH is also shown in Figure S1. One can see that the triplet peak \(d\), which is assigned to methylene protons next to the oxygen atom (-\(\text{CH}_2\text{O}\), \(\delta = 3.60\) ppm) in the \textsuperscript{1}H-NMR of PE-OH (I in Figure S1), is vanished in the \textsuperscript{1}H-NMR of PE-macroinitiator (II in Figure S1). The appearance of three new peaks (\(d'\) (-\(\text{CH}_2\text{O}\), \(\delta = 4.18\) ppm), \(e\) (-\(\text{C}(\text{CH}_3)_2\text{Br}\), \(\delta = 1.95\) ppm) and \(c'\) (-\(\text{CH}_2\text{CH}_2\text{O}\), \(\delta = 1.67\) ppm)) in II of Figure S1 indicated that the \(\alpha\)-haloester end-capped polyethylene was formed. The integral ratio of peak \(d'\) to peak \(e\) was 1/3. Besides, the integral ratio of peak \(d'\) to peak \(a\) in PE-macroinitiator was the same with that of peak \(d\) to peak \(a\) in PE-OH. All of the information shown above proved that the esterification of PE-OH proceeded quantitatively (\(\sim 100\%\)).

The ATRP of \(\text{tBA}\) was conducted in toluene with CuBr/PMDETA as catalyst. Monomer conversion was monitored by \textsuperscript{1}H-NMR by comparing the integrals of the triplet peak \(d''\) at \(\delta = 4.26\) ppm from PE-macroinitiator (-\(\text{CH}_2\text{O}\)) (III in Figure S1) and the peak \(g\) at \(\delta = 2.67\) ppm (III in Figure S1), which is attributed to the protons
located at the backbone of PrBA. As shown in Table 1, the conversion of monomer is about 30% and this may attributed to the high viscosity of the reaction product in toluene at the late reaction stage; By changing the molar ratio of tBA to the macroinitiator, three BCPs, PE$_{100}$-PrBA$_{30}$, PE$_{100}$-PrBA$_{48}$ and PE$_{100}$-PrBA$_{70}$ (where the subscripts refer to the polymerization degrees of PE and PrBA) were synthesized. As shown in Figure S2, the molecular weight of the BCPs increases with the increasing length of the PrBA block. The PDIs of the obtained PE-\textit{b}-PrBA BCPs were slightly larger than that of PE-macroinitiator, but were still in an acceptable range (Figure S2 and Table S1).

**Figure S1.** $^1$H-NMR spectra of PE-OH (I), PE-macroinitiator (II) and PE-\textit{b}-PrBA (III) (* solvent).
**Figure S2.** GPC profiles of PE based block copolymers.

**Table S1.** Sample information of PE-OH and PE-\(b\)-PrBA BCPs.

Figure S3. WAXD pattern of dried PE$_{100}$-b-PtBA$_{30}$ micelles, the micelles were prepared in DMF (5mg/ml) at $T_c$ of 25 °C. Three diffraction peak were obtained in the PE$_{100}$-b-PtBA$_{30}$ micelles solution and can be indexed into the (210) reflection, (020) reflection and the (011) reflection of the typical polyethylene orthorhombic unit cell. \textsuperscript{3}
Figure S4. DSC crystallization curves of the PE-b-PtBA/DMF (1/0.63 w/w) mixtures. The cooling rate is 1 °C/min.

Because of the low sensitivity of DSC, the PE-b-PtBA/DMF mixtures with a high BCP concentration, instead of the micellar solutions with a low BCP concentration, were used for DSC experiments. Moreover, since growth of the crystalline micelles was isothermally performed at a $T_{c}$, a slow cooling rate (1 °C/min) was applied to the non-isothermal DSC experiments for selection of suitable $T_{c}$s.

Figure S6. Outlines of the long PE-b-PrBA micelles after growth at $T_{c} = 90 \, ^\circ\text{C}$ for 60 h. (a) PE$_{100}$-b-PrBA$_{30}$, (b) PE$_{100}$-b-PrBA$_{48}$, (c) PE$_{100}$-b-PrBA$_{70}$. 
The stretching exponential function is used to describe the electric field autocorrelation function:

\[ g'(t) = A_{\text{fast}} \exp(-t/\tau_{\text{fast}}) + A_{\text{slow}} \exp\left[-(t/\tau_{\text{slow}})\gamma\right] \]  

(S4)
where $\tau_{\text{fast}}$ and $\tau_{\text{slow}}$ are the relaxation times of the fast and slow motions, respectively. The stretched exponent $\gamma$ is inversely proportional to the distribution width of the decay time. The pre-factors $A_{\text{fast}}$ and $A_{\text{slow}}$ are the amplitudes of the fast and slow relaxation modes, respectively, and the sum of $A_{\text{fast}}$ and $A_{\text{slow}}$ is close to 1.

At $T_c=25$ °C, no stepwise crystallization occurs and the short cylindrical micelles are directly formed via simultaneous micellization/crystallization of the unimers. However, a bimodal size distribution is still observed for the micelles at $T_c=25$ °C. As the number of the short cylindrical micelles generated via micellization/crystallization of the unimers is much larger than the micelles generated through crystallization of the amorphous spherical micelles, the scattering signal from these two kinds of micelles can be separated easily. The fast relaxation mode is assigned to micelles formed by crystallization of the amorphous spherical micelles, and the slow relaxation mode is attributed to the cylindrical micelles formed by the unimers. On the other hand, at $T_c$s above 25 °C, both short and long cylindrical micelles co-exist in the BCPs solution. These short cylindrical micelles are formed through crystallization of the amorphous spherical micelles and micellization of the unimers when being cooled from various $T_c$s to 25 °C. As most of the unimers are consumed at $T_c$, fewer micelles are formed through micellization/crystallization of the unimers when being cooled from various $T_c$s, so the scattering intensity from the micelles formed by crystallization of the amorphous spherical micelles and short cylindrical micelles cannot be separated. The fast relaxation mode is assigned to the motion of the micelles formed via micellization of un-consumed unimers and the micelles formed by crystallization of the amorphous spherical micelles, while the slow relaxation mode corresponds to the motion of the long cylindrical micelles formed at $T_c$. When
the micelles have the same shape, the relaxation time can be correlated to the micellar size. The larger the micellar size, the larger the relaxation time.

The fitting results of the electric-field autocorrelation functions at the scattering angle of 90° are shown in Figure S8 and the obtained parameters are summarized in Table S2. It is found that, the τ<sub>slow</sub> of PE<sub>100</sub>-b-PtBA<sub>70</sub>, which corresponds to the relaxation time of the long cylindrical micelles, increases with raising T<sub>c</sub>. Moreover, at T<sub>c</sub>=90 °C, the τ<sub>slow</sub> increase rapidly as the PtBA block becomes longer. This indicates that the long cylindrical micelles have a larger dimension in length at a higher T<sub>c</sub> and for the PE-b-PtBA with a longer corona-forming block, which is in accordance with the TEM result. By contrast, the value of τ<sub>fast</sub>, which is the relaxation time of the micelles formed by unimers and amorphous spherical micelles at 25 °C, does not change greatly with T<sub>c</sub> and the length of PtBA block. This implies that there is no big difference in the length of the formed short cylinders when the unimers of different PE-b-PtBA BCPs are cooled from various T<sub>c</sub>s. On the other hand, the parameter A<sub>slow</sub>, which represents the fraction of the long cylindrical micelles formed
through growth of the unimers on the seed micelles at $T_c$, decreases with increasing the length of PrBA block at $T_c=90$ °C and $T_c$ for PE$_{100}$-$b$-PrBA$_{70}$. This shows that fewer long micelles are formed when the PrBA block is longer and $T_c$ is higher. This is understandable, since the solubility of the PE-$b$-PrBA is better at a higher $T_c$ or for a BCP with a longer corona-forming block, a smaller amount of seed crystalline micelles are formed through the stepwise micellization/crystallization process of the unimers at $T_c$. By contrast, as the length of PrBA block is changed, $A_{\text{fast}}$ exhibits a tendency opposed to $A_{\text{slow}}$. This means that more short micelles are formed when a longer PrBA-containing BCP is cooled to 25 °C after growth at $T_c=90$ °C for 60 h. This is probably because more unimers are left in the solution of PE$_{100}$-$b$-PrBA$_{70}$ after growth at $T_c=90$ °C for 60 h due to its better solubility in DMF and slower growth rate, as the growth rate of BCP micelle with longer coronal-forming block is slower. Moreover, for PE$_{100}$-$b$-PrBA$_{70}$ after growth for 12 h, $T_c$ has no significant effect on $A_{\text{fast}}$.
