A study of the impact of co-adsorbents on DSSC electron transfer processes:

anti-π-staking vs. shield effect

The amount of N719 grafted on the co-adsorbent free cells has been measured after desorption of the dye from the TiO$_2$ layer using 4 M KOH solution, and subsequent measurement of the optical density of the obtained solution at 530 nm, taking into account the value of the molecular extinction coefficient, near 14200. The surface concentration has been calculated dividing this mole amount by the external area of the cell, here 6 x 6 mm$^2$.

Because the two co-adsorbents employed are perfectly transparent at the working wavelength, it has been considered that the optical density was solely due to the presence of the dye, whose surface concentration was directly estimated from the OD. Moreover, the projected area of the sensitizer can be estimated from a drawing software to range between 80 and 100 Ångström$^2$. The surface covered by the dye was calculated from the above surface concentration and the projected area of this molecule, taking into account the Avogadro number.

The real surface of the TiO$_2$ layer was estimated from the thickness of the layer (5 µm), the surface area of the material, in the order of 50 m$^2$/g and the density of the SC layer, taken at 2.8 g/cm$^2$ from the density of titanium oxide and the porosity of the particle layer. The surface area of TiO$_2$ substrate was then in the order of 700 cm$^2$ cm$^{-2}$. The coverage fraction was finally obtained by dividing the two above surface. The values reported in the above tables have to be taken with care, because of the assumptions made; however they can be sued for comparison purpose between the various co-adsorbent N719 dye combinations.
Current density vs. voltage curves of DSSC prepared with various co-adsorbent/N719 ratios.

NB. These curves are the average of the data produced with the three replicate cells, for all co-adsorbent-dye combinations.
