Synthesis of the materials

The homoionic Na\(^+\)-saturated montmorillonite (Na-montmorillonite, Na-Mont) and Al-pillared montmorillonite (Al-montmorillonite, Al-Mont) were synthesized by a simple cation exchange procedure. Herein, the raw Ca-montmorillonite (Ca-Mont) without size fraction was directly used to synthesize these supports [1]. For Na-Mont, concretely, ~10.0 g of Ca-Mont was dispersed in ~150 mL of NaCl solution and shaken at ~200 rpm, ~25 °C for ~10 h, then the suspension was centrifuged and the supernatant was discarded. The collected sample was re-suspended in ~150 mL of NaCl solution, then shaken and centrifuged as above. Five times repetitions were done to ensure complete Na\(^+\) saturation. Finally, the Na\(^+\)-saturated product was washed with de-ionized water until no Cl\(^-\) was detected in the filtrate [1]. Then, we used the
as-synthesized Na-Mont to synthesize Al-Mont support. First, the pillaring solution was prepared by adding NaOH into ~0.20 mol/L AlCl$_3$, until the molar ratio of [OH$^-$]/[Al$^{3+}$] achieved to be ~2.0. Then the pillaring solution was slowly added into ~10.0 g of Na-Mont suspension under continuous stirring in a water bath, the formed product was centrifuged and the supernatant was discarded. Then, the product was washed with de-ionized water until no Cl$^-$ was detected in the filtrate, and finally dried in an oven. Before utilization, Na-Mont and Al-Mont were mechanically ground to a size of less than 100 meshes, and activated at ~110 $^\circ$C for 2 h [1-3].

The nanoscale zero valent iron (NZVI) was synthesized by a chemical reduction procedure [2-4]. In brief, ~0.15 mol/L NaBH$_4$ was slowly added into ~0.05 mol/L FeSO$_4$·7H$_2$O under continuous stirring. Then the solution was stirred for ~30 min under room temperature. The NZVI particles formed were settled and separated from the liquid phase by vacuum filtration using Whatman (blue band) filter papers. Then the formed NZVI was washed with ethanol for several times, and finally vacuum-dried. The NZVI/Na-Mont and NZVI/Al-Mont composites were synthesized by a similar procedure for the preparation of NZVI, except that, before the addition of NaBH$_4$, ~10.0 g of Na-Mont or Al-Mont were uniformly mixed with 300.0 mL of 0.055 mol/L FeSO$_4$·7H$_2$O solution under continuous stirring. The as-synthesized iron sources were stored in N$_2$ atmosphere to prevent atmospheric contamination and oxidation [4]. The iron contents of the different reactive materials, using the atom absorption spectra in a Shimadzu AA-6300 spectrophotometer, were measured to be 90.8 % for ZVI, 52.6 % for NZVI, 21.5 % for NZVI/Al-Mont, and 20.2 % for
Macroscopic measurements

The macroscopic measurements for U(VI) and Se(IV) sequestration onto various iron sources were carried out in a 100-mL conical flask in a water bath incubator of ~20 °C under N₂ conditions by using batch experiments. Typically, each sample containing a certain amount of iron was added into the conical flask with 100 mL of U(VI) or Se(IV) solution, which was deoxygenated by N₂ stream. The conical flask was sealed with a stopper during the experiment. The reaction was carried out by putting the flask in a thermostatic shaker bath. At given time intervals, a series of samples were withdrawn and filtered through 0.22-μm membrane for determination of U(VI) or Se(IV) concentrations. The concentration of U(VI) was determined by the arsenazo(III) spectrophotometric method at the wavelength of 650 nm [2, 4]. The concentrations of Se(IV) were analyzed by using Hydride generation atomic absorption spectrometry (HG-AAS, AA-6300 C, Shimadzu) [3]. The removal of U(VI) or Se(IV) was calculated: removal(%) = (C₀−Cₜ)/C₀×100%.

The adsorption isotherms of U(VI) or Se(IV) on Na-Mont and Al-Mont were determined. U(VI) or Se(IV) solution at various initial concentrations was mixed with a certain amount of Na-Mont and Al-Mont. All batch experiments were carried out in a thermostatic shaker bath. After adsorption equilibrium, the suspension was centrifuged, the supernatant was filtered through 0.22-μm membrane for determination of U(VI) or Se(IV) concentration. The adsorbed amounts (qₑ(mg/g)) of
U(VI) or Se(IV) on Na-Mont and Al-Mont were calculated from the difference between initial \( (C_0\text{ (mg/L)}) \) and equilibrium \( (C_e\text{ (mg/L)}) \) concentration according to the equation, 
\[
q = \frac{(C_0 - C_e) \times V}{m},
\]
where \( V \) is the total volume of suspension (mL), and \( m \) is adsorbent mass (g).

**Characterization methods**

Scanning electron microscopy (SEM) images were obtained on a JSM-6360LV microscope instrument. Transmission electron microscope (TEM) images were obtained in a JEM-1010 instrument using an accelerating voltage of 80 kV. X-ray diffraction (XRD) measurement was performed with a Rigaku D/MAX-2500 system using Cu Ka radiation at 0.1542 nm. The zeta potential was measured by nano-ZS model (Malvern) zetasizer instrument. XPS spectra were collected using a Thermo ESCALAB 250 with a monochromatized Al Ka X-ray source \( h\nu = 1486.6 \text{ eV} \) operated at a power of 150 W and a constant pass energy of 20 eV for the analyzer. The binding energies of the photoelectrons were corrected by C 1s peak at 284.8 eV. The Brunauer–Emmett–Teller (BET) specific surface areas were obtained from nitrogen adsorption data at 77 K in a Micromeritics ASAP 2020 system. The solution pH was measured with a pH meter (PHS-2C, China). U L_{\alpha}-edge X-ray absorption fine structure (XAFS) spectra at \( \sim 17166 \text{ eV} \) and Se K-edge XAFS spectra at \( \sim 12684.5 \text{ eV} \) for the solid products were recorded at the beamline 14W in Shanghai Synchrotron Radiation Facility (SSRF, China). The electron beam energy was 3.5 GeV and the mean stored current was 300 mA. All spectra were collected in fluorescence mode.
using a multi-element pixel high purity Ge solid-state detector. Scans were collected in triplicate and averaged to improve the signal-to-noise ratio. Analysis of extended X-ray absorption fine structure (EXAFS) and X-ray absorption near edge structure (XANES) was performed using Athena and Artemis interfaces of the IFFEFIT software [5, 6]. First, the averaged spectra were normalized with respect to $E_0$ determined from the second derivative of the raw spectra, and then the total atomic cross-sectional absorption was set to unity. A low-order polynomial function was fit to the pre-edge region and the post-edge region. Next, the data were converted from E-space to $k$-space and weighted by $k^3$ to compensate for dampening of the XAFS amplitude with increasing $k$ space. Fourier transformation was then performed over the $k$ range of 2.0-10.0 Å$^{-1}$ using the Kaiser-Bessel window function to obtain the radial structural functions (RSFs). Final fitting of the spectra was done on Fourier transformed $k^3$-weighted spectra in R-space. Theoretical EXAFS amplitude and phase functions for Se-O, Se-Se, Se-Fe and U-O, U-U, U-Fe and U-Al/Si single scattering paths were generated by FEFF 7.0 [7]. Fitted parameters such as interatomic distance ($R$), coordination number (N) and Debye-Waller factor ($\sigma^2$) were first established with reasonable guesses and were fitted in R-space.
