**S1. Raman spectroscopy for identification of number of layers in MoS\textsubscript{2} film**

To support observations by optical contrast, well known Raman spectroscopy technique is used to identify monolayer and bilayer MoS\textsubscript{2} films, by finding the separation between E\textsubscript{12g} and A\textsubscript{1g} peaks. The separation for monolayer and bilayer are found to be 18.67 cm\textsuperscript{-1} and 21.53 cm\textsuperscript{-1}, respectively. Larger separation is expected for thicker layers.

Figure S1. Raman signal of monolayer and bilayer MoS\textsubscript{2}, measured after the formation of the device.
S2. Photoluminescence characterization of MoS$_2$ samples with varying number of layers

Figure S2. Thickness dependent photoluminescence signal of MoS$_2$, with a 532 nm excitation.

The A peak at the K point shows clear dependence of the PL intensity with thickness.
S3. Band diagram in MoS$_2$ monolayers and heterojunctions

The band diagrams are calculated by solving Poisson equation:

$$\frac{d^2 \phi(x)}{dx^2} = \frac{q[n(x) - p(x) + N_a - N_d]}{\varepsilon_0 \varepsilon_r}.$$ 

$\varepsilon_r$ is assumed to be 5. We assumed two band model with 2D density of states: 

$$D(E) = \frac{m^*}{\pi \hbar^2}$$ 

with degenerate spin up and spin down states. The electron density $n(x)$ is obtained from:

$$n(x) = \int_{E_c}^{\infty} dE f(x,E)D(E)$$

$$f(x,E) = \frac{1}{1 + e^{[E - F(x)]/k_B T}}$$

where $F(x)$ is the local quasi-Fermi level. The hole densities are also found similarly. In the absence of any intentional doping or external gate voltage, the relatively large electrical band gap of the monolayer results in small net charge, and hence weak band bending, as shown in Fig. S3. We have used four different doping conditions, and $V_{ds}=0$. The bandgap in this example has been assumed to be 1.9 eV, although it is important to keep in mind that the electrical bandgap can be higher than this value, depending on the strength of the exciton binding energy. We have also assumed a Fermi level pinning of the metal contacts at 0.25 eV below the conduction band. The predicted quasi-linear bands in Fig. S3 are arising due to the presence of low carrier density which does not allow strong band bending.

In the case of heterojunctions, the calculation remains similar, with the band offsets are added appropriately. There are varying reports on the exact magnitude and direction of the band offsets between monolayer and multi-layer [1,2]. In this work, we have taken the values from [2], but we report the energy scale in arbitrary unit in the absence of a consensus on these values.
Figure S3: Band diagram of monolayer MoS$_2$, with $V_{ds}=0$, and four different n-type doping conditions. The Fermi-level is at zero energy. Metal Fermi-level is assumed to have been pinned at 0.25 eV below the conduction band minimum.
S4. Scanning photoluminescence characterization of MoS$_2$ heterojunctions

Figure S4: Scanning photoluminescence intensity across 1L/2L and 1L/FL/ML MoS$_2$ heterojunction.
S5. AFM thickness characterization of MoS$_2$ heterojunctions

Figure S5: Measured thickness of 1L/2L and 1L/FL/ML MoS$_2$ heterojunctions using AFM.
S6. Scanning photocurrent measurement for few-layer/multi-layer heterojunction device and uniform multi-layer device

Figure S6: Scanning photocurrent in (a) few-layer/multi-layer (FL/ML) heterojunction with $L=8.2 \, \mu m$ and $W=4.5 \, \mu m$, and (b) multi-layer (ML) homojunction, with $L=6.7 \, \mu m$ and $W=1.9 \, \mu m$. The scans have been performed at different $V_{ds}$, in steps of 0.1 V. The laser power used is 2.6 $\mu W$. 
S7. Transient response of a monolayer MoS$_2$ photodetector

Figure S7. Transient response of a monolayer MoS$_2$ photodetector, with larger fall time (90% to 10%), in excess of 100 s, due to strong hole trapping.
