Experimental Procedures

The chemicals are of analytical grade and were used as received without further purification.

**Synthesis of IrO$_2$, MnO$_2$ and Ir/Mn composites:** The different ratios between Ir and Mn were achieved by varying the concentration of the Ir or Mn precursor. In a typical procedure, 113.4 mmol L$^{-1}$ Mn(NO$_3$)$_2$ and 56.7 mmol L$^{-1}$ H$_2$IrCl$_4$ with required amount were mixed in 50mL autoclave, and kept 5min for peroxidation of Mn after addition of 500uL 30% H$_2$O$_2$. Then 15mL 0.66M NaOH was added, resulting in drastic decomposition of H$_2$O$_2$ and successive formation of indissoluble solid. The mixture was aged for 10min. No surfactant was added in this system to gain greener synthesis approach. The autoclave was sealed tightly and slowly heated in an oven to 220°C. The solution was kept for 12 hours to gain fine crystals, and then naturally cooled down to room temperature. The precipitate was collected, suction filtered and washed several times with deionized water to remove residual ions. The retentate on the filter was dried for dehydration in an oven at 80°C for 1h. The final sample was collected and annealed at 400°C for 6 h to produce excellent crystallinity. As for IrO$_2$, the synthetic procedure is similar with the preparation of Ir/Mn composite. The only difference is that no Mn precursor is added. As for MnO$_2$, the synthetic procedure is similar with the preparation of Ir/Mn composite with the only difference being no Ir precursor added.

The synthesis of Ir/Mn composites can be explained by a two-step reaction. Mn(OH)$_2$ is formed in the first step by reaction of Mn$^{2+}$ with OH$^-$, and is oxidized by H$_2$O$_2$ to birnessite in the subsequent step. Insertion of cations and H$_2$O molecules into the interlayers accompanies oxidation of Mn$^{2+}$ to higher valence state.

**Insight of synthesis procedure with help of Inductively Coupled Plasma Atomic Emission Spectrometer (ICP-AES) Experiments:** Before the hydrothermal synthesis of the Ir0.3/Mn0.7 composite, the Mn precursor and Ir precursor were firstly mixed with H$_2$O$_2$. Then solution was added with 15mL 0.66M NaOH and kept for 10min before sampling for ICP analysis (step1 in Fig S2). After that, the mixture was aged for another 12 hours (step2 in Fig S2). This step is similar to synthesis of birnessite manganese oxide which has been reported previously.$^1$ Then the mixture was transferred to an autoclave and hydrothermally heated at 80°C for 8 hours (step3 in Fig S2). Finally, the mixture was kept in the hydrothermal system at 220°C for another 12 hours ($t_{final}$). Every ICP sample was extracted from supernatant, and the
pH was adjusted to acid with 0.1M HCl solution. Actually, IrO$_2$ precipitated at 220°C, not at 80°C. We take 80°C into consideration here to describe the forming sequence of IrO$_2$ and MnO$_2$.

**Electrode preparation:** To prepare the working electrode, catalyst inks were deposited on Ti plates. The catalysts (weighted at 6.0mg) were ultrasonically dispersed in 1.5 mL isopropanol / deionized water (2:1 v/v) with 15uL 5% Nafion solution as solvent. The Ti plates (5mm×15mm) were used as supports and pre-cleaned by etching in 10wt % faint boiling oxalic acid for 2 h. Then 7.5uL of each catalyst ink was taken and drop-cast onto the pre-cleaned Ti plate. The catalyst layer on the Ti plate was dried at 60°C for 10min. The process was repeated five times, leading to the total loading at 0.2mg cm$^{-2}$. A saturated calomel electrode (SCE) electrode and a polished Pt foil were used as the reference electrode and counter electrode, respectively.

**Electrocatalytic Study:** The OER performance of the composite materials was investigated by using electrochemical techniques since oxygen evolution behavior is directly proportional to electrons transference. The electrolyte (0.1 M HClO$_4$) was prepared by dilution of 70% perchloric acid with DI water. Electrocatalytic measurements were carried out with a standard three-electrode electrochemical cell controlled by a CHI660E workstation. As no rotation applied, the O$_2$ bubble nucleation generated from OER process may partly cover the electrode active surface. At the beginning of the electrocatalytic study, the electrodes were cycled between -0.2 and 1.4 V (vs. SCE) at a scan rate of 50 mV s$^{-1}$ until the curve values reached stable, leading to steady surface conditions. The polarization curves were obtained by extending the potential up-limit to 1.4V (vs. SCE) scanning at a rate of 10mV s$^{-1}$. The Tafel plots were got from the staircase voltammetry measurements, in which the potential was progressively elevated by 10 mV steps, and each step was kept for 100 s. As the current values were read at the end of each step, the effect of capacitive current was effectively eliminated. The Ir loading in the IrO$_2$/MnO$_2$ composites are based on the Ir/Mn atomic ratios. For catalysts with porous or layered morphology, the intrinsic electrocatalytic ability should take surface area into consideration, as the active sites are extensively exposed. The electrochemical surface area (ECSA) is proportional to the active sites involved in electrochemical reactions, thus generally considered to be a significant parameter for the high OER performance. Here, the cyclic voltammograms (CVs) were carried out to determine the ECSA by measuring the charging currents of double-layer capacitance at different scan rates. For CVs within 0.1-1.4 V$_{RHE}$, the curves in some potential regions show oxidation/reduction peaks, which are mainly Faradaic currents ($I_F$) for the change of Ir or Mn oxidation states. The flat parts with no distinct peaks are contributed from the charging currents ($I_C$). To investigate
the CVs at low Faradaic current contribution, CVs were additionally recorded for Ir0.4/Mn0.6 and IrO₂ between 1.1 V and 1.4 V (vs. RHE) with scan rates of 10, 20, 40, 60, and 80 mV s⁻¹.

To investigate the CVs at low mass transfer resistance, the electrochemical impedance spectroscopy (EIS) measurements were performed in a three-electrode electrochemical cell in a rotating-disc electrode (RDE) configuration. The potential was set at 1.25V vs. SCE (1.49 V vs. RHE), with range of frequency set as 0.1 – 10⁵ Hz and applying the amplitude of 10 mV RMS. To simulate the equivalent resistances and capacitance, impedance data were fitted, and real (Z') and imaginary (Z'') components in the Nyquist plot were analyzed using Zview software (Scribner Associates Inc.). To adjust the RDE system, the working electrode is a little different, and catalysts were deposited on glassy carbon (surface area of 0.196 cm²). The electrodes were kept for 100 s at the set potential to establish stable current response before recording each spectrum.

The electrode potential was converted from the SCE scale to the reversible hydrogen electrode (RHE) scale by following calibration:

\[ E \text{ (RHE)} = E \text{ (vs. SCE)} + 0.2415 + 0.0596pH - iR \]  

(1)

where i is the current at the applied potential, and R is the uncompensated Ohmic electrolyte resistance measured by electrochemical workstation. The over-potential values (η) were obtained using the following equation:

\[ \eta = E \text{ (RHE)} - 1.229V \]  

(2)

The values of mass activity (A g⁻¹) and turnover frequency (TOF, s⁻¹) were calculated, and calculation details are as follows:

\[ \text{Mass activity} = \frac{j}{m} \]  

(3)

\[ \text{TOF} = \frac{(j \times S)}{(4 \times F \times \eta)} \]  

(4)

Here, j is the average current density at a given potential, m is the Iridium loading (for IrO₂ is 0.857× 0.2 mg cm⁻²) of the electrode. S is the geometric area of the working electrode (0.25 cm²), the number 4 represents the electrons transfer in oxygen molecule generation, F means Faraday’s constant (96485 C mol⁻¹), and n is the moles of coated Iridium atoms. This calculation assumes that every Iridium atom (rather than Mn) is involved in oxygen evolution.

In the measurement of ECSA, the CVs were carried out in a potential range where no Faradaic processes take place at scan rates ranging from 10 to 80 mV s⁻¹. In this way, the measured currents were mainly contributed by charging current (i_c). The charging currents show linear relationship with the scan rates:

\[ i_c = C_d \nu \]  

(5)
in which \( C_d \) is capacitance of the double layer and \( v \) is the applied scan rate. So one can estimate the ECSA using the following equation:

\[
e\text{-ECSA} = \frac{C_d}{C_s}
\]  

(6)

in which the \( C_s \) is the specific capacitance of an electrode. For estimation of surface area here, we use general specific capacitances of \( C_s = 0.035 \text{ mF cm}^{-2} \).
Scheme S1. Synthesis of Ir/Mn composites.
The layered birnessite MnO$_2$ is formed at room temperature (R.T.), and IrO$_2$ is formed in hydrothermal reaction. The process A and B are suppositional processes during hydrothermal reaction. A: anchoring and growing of the Ir oxide; B: twisting of the nano-plates.

ACKNOWLEDGMENT

This research is based on the work supported by the National Natural Science Foundation of China (51778229) and the “Shu Guang” project of the Shanghai Municipal Education Commission. We thank beamline BL14W1 (Shanghai Synchrotron Radiation Facility, Shanghai) and Catalysis and Surface Science Endstation (National Synchrotron Radiation Laboratory, Hefei) for providing the beam time.

The data are from Platinum group metals (PGM) market reports from Johnson Matthey.\textsuperscript{2, 3}
Fig S2. The forming sequence of IrO$_2$ and δ-MnO$_2$ revealed by ICP analysis
Firstly the Mn precursor and Ir precursor were mixed with H$_2$O$_2$ ($t_0$). Then solution was added with 15mL 0.66M NaOH. The solution was kept for 10min before sampling for ICP analysis (S1 in Fig. S2 for treatment step1). After that, the mixture was aged for another 12 hours (S2). Then the mixture was transferred to an autoclave and hydrothermally heated at 80$^\circ$C for 8 hours (S3). Finally, the mixture was kept in hydrothermal system at 220$^\circ$C for another 12hours ($t_{\text{final}}$). Note that, treatment step3 (S3) at 80$^\circ$C is applied to further prove that the formation of Ir oxide lags behind, though the synthesis approach of the catalysts does not involve this step. Here, C$_0$ represents the initial concentration of Mn or Ir.

(d, e) The Ir loading-normalized Tafel plots for all IrO₂/MnO₂ composites. The curves in (d, e) are got by eliminating the OER current with respect to the corresponding Ir loading ratio (for IrO₂ is 0.857).

**Supplementary Note S1. The mechanism of OER in acid**

In acidic environments, the so-called electrochemical oxide path is described as\(^4, 5\):

\[
\begin{align*}
&M + H_2O = M-OH_{ads} + H^+ + e^- \quad \text{(step R1)} \\
&M-OH_{ads} = M-O_{ads} + H^+ + e^- \quad \text{(step R2)} \\
&2M-O_{ads} = 2M + O_2 \quad \text{(step R3)}
\end{align*}
\]

where M represents active metal surface site, and M–OH\(_{ads}\), M–O\(_{ads}\) are two type adsorption intermediates. Tafel analysis is generally utilized to elucidate specific rate determining step (RDS) of surface reaction. According to the formal kinetics analysis, if step R2 representing the deprotonation of the reaction intermediate OH\(_{ads}\) controls the overall reaction rate, then for low surface coverage by intermediates OH\(_{ads}\) and O\(_{ads}\), i.e. at low current densities, the theoretical Tafel slope (b) of 40 mV/dec is obtained. Similarly, if step R3 controls the overall reaction rate, 30 mV/dec is theoretically obtained. The Tafel slopes for IrO₂ and Ir/Mn composites, which were obtained from
Tafel plots, are listed in Table S3. At low current densities, the b values for homemade and commercial IrO$_2$ are about 56 mV/dec, in accordance with the values mentioned in the literature. However, the Ir/Mn composites show much lower slopes (in the range of 40-44 mV/dec) indicating a faster reaction pathway. The above-listed mechanism predicted from Tafel slopes reveals that the RDS for the Ir/Mn composites is deprotonation of the reaction intermediate OH$_{ads}$. For IrO$_2$ with a commonly observed b value of 60 mV/dec, the RDS is neither located at step R2 nor R3. According to the Hu group’s research on the kinetics analysis of Tafel lines for IrO$_2$, it is assumed that step R1 is substituted by two sub-reactions:

$$M + H_2O = M–OH^*_{ads} + H^+ + e^- \quad (R1')$$

$$M–OH^*_{ads} = M–OH_{ads} \quad (R1'')$$

in which M–OH$^*_{ads}$ and M–OH$_{ads}$ as adsorption intermediates possess the same chemical structure, but have different energy states.$^6$ In their simulation of Tafel lines with a 60 mV/dec slope, the OER is found to be completely controlled by step R1. Thus, in conclusion, the RDS for the Ir/Mn composites is different than that for IrO$_2$. The presence of unpaired electrons in the e$_g$ orbitals of the Ir/Mn composites may facilitate the cleavage of the O–H bond in OH$_{ads}$ and promote the formation of M–O$_{ads}$ (step R2).
**Fig S16.** Normalized cyclic voltammogram curves.

Normalized cyclic voltammogram curves (potential within 0.10V-1.45V) with different scan rates of (a) Ir0.4/Mn0.6 and (b) homemade IrO$_2$ in 0.1 M HClO$_4$. The dotted circles show the region where Faradaic currents occur, reflecting the change of metal oxidation states. The Faradaic currents at about 1.437V in (a) reveal the onset of OER.
**Fig S17.** The cyclic voltammogram curves with different scan rates.

The cyclic voltammogram curves with different scan rates of (a) homemade IrO$_2$ and (b) Ir0.4/Mn0.6 in 0.1 M HClO$_4$. For a given potential (here is 1.25V vs. RHE) where the curves are flat, slopes of the current to scan rate are plotted in (c). The current shows linear relationship with the scan rate, and absolute value of the slope is $C_{dl}$. The average $C_{dl}$ for IrO$_2$ is 5.0 mF, and for Ir0.4/Mn0.6 is 11.6 mF. The $C_{dl}$ determined here is similar to EIS fit results (ESI, Table S2).
**Fig S18.** The oxide specific activity normalized to electrochemical surface area of Ir0.4/Mn0.6 and IrO₂ in acidic electrolyte.

The activity is normalized to ECSA determined by $C_{dl}$ at 1.49V (see EIS fit, Table S2). Based on this, the intrinsic activity of Ir0.4/Mn0.6 that is 5.6 times higher than that of pure IrO₂ when normalized to electrochemical active surface area.
Fig S19. Comparison of the Ir 4f peak intensity of IrO$_2$ and Ir$_{0.3}$/Mn$_{0.7}$. 
Fig S20. Mn2p spectra of Ir0.3/Mn0.7 and δ-MnO₂.
The peaks A1, B1 at ~641.1 eV, and A3, B3 at ~651 eV correspond to Mn³⁺. The peak A2, B2 at ~642.3 eV, and A4, B4 at ~654 eV correspond to Mn⁴⁺. A1-A2, and B1-B2 represent for the Mn 2p3/2 peaks, the A3-A4, B3-B4 for Mn 2p1/2 peaks.
Fig S21. Ir4f and Mn3s spectra of Ir0.3/Mn0.7.
Supplementary Note S2. The discussion on XPS

Figures S19–22 present typical XP spectra for the synthesized catalysts (Ir0.3/Mn0.7, IrO2 and δ-MnO2). The deconvoluted component spectra of Ir4f for Ir0.3/Mn0.7 and IrO2 (Fig. S19, 21) are almost the same with two symmetrical peaks at about 61.78 eV for Ir 4f7/2 and 64.78 eV for Ir4f5/2, showing mainly the Ir4+ form. The XPS analysis of Ir0.3/Mn0.7 and δ-MnO2 reveals that the oxidation states of Mn are lower than 4+ form (Fig S20, 21). The spectra of O1s photoelectrons in Ir0.3/Mn0.7 depicted in Fig. S22 consist of three components (ca. 529.3, 530.5, and 532.1 eV), which are due to the oxygen in the oxides crystal lattice (M-O, M=Metal), chemisorbed oxygen via surface hydroxyl (O–), and the oxygen in adsorbed water in the atmosphere (O2–). The oxygen energy states of Ir0.3/Mn0.7 composite shows is between IrO2 and MnO2, which is middle state of the mixed oxides. This is in accordance with the catalyst structure of IrO2 loaded MnO2. X-ray photoemission spectrum (XPS) reveals that the composite has plenty of surface IrIII, MnIII and hydroxyl oxygen defects.

A reliable distinction for Mn oxidation state should be the degree of Mn-3s peak splitting that is caused primarily by the exchange interaction of non-ionized 3s electrons with 3d valence-band electrons. Generally, Mn-3s peak splitting width of about 4.5eV can be diagnosed for MnO2, about 5.5eV for Mn2O3 or Mn3O4, and about 5.9eV for
MnO. For δ-MnO₂, the Mn-3s splitting width is 4.7eV, revealing an oxidation state slightly lower than 4+. For Ir0.3/Mn0.7, the Mn-3s splitting width is higher than the δ-MnO₂, which indicates that the average Mn oxidation state has decreased and lies between +3 and +4. As for the Mn-2p spectrum (Figure S20) of δ-MnO₂, the peak B1 at 641.1 eV corresponds to Mn^{III}, and the peak B2 at 642.3 eV to Mn^{IV}. After coupling with IrO₂, the Mn-2p spectrum of Ir0.3/Mn0.7 exhibits a significant negative shift of the peak A2, confirming a lower chemical oxidation of Mn.

Note: The equivalent circuit applied for fitting the impedance spectra of Ir/Mn composites is shown in Fig S14 inset. The impedance spectra of Ir/Mn samples were fitted by the so-called constant phase element (CPE) model comprising one constant phase element, with a constant phase element in parallel with a resistor. The true capacitance from this depressed semicircle model can be calculated by the following equation:\(^{9-12}\):

\[ C_{CPE-dl} = \left[ Y \left( \frac{1}{R_u} + \frac{1}{R_{ct}} \right)^n - 1 \right]^{1/n} \]  

In which C, Y, R_{ct}, R_u and n indicate the specific capacitance (F. cm²), a constant with dimension (S. s⁰ cm⁻²), ionic charge-transfer resistance (Ω. cm²), the ohmic resistance of solution (Ω. cm²) and a constant without dimension, respectively. Considering the impedance of a CPE is represented as \( Z(\text{CPE}) = 1/(i\omega)^n Y \) (\( \omega \) is the frequency of the sinusoidal applied potential, \( i = (-1)^{1/2} \)), the units of Y are “S s^n cm⁻²”.

[a] Basing on the Ir-Ir first shell distances got from Ir EXAFS, the values of c-axis length are estimated.

[b] From Ir EXAFS spectra, the distance of Ir-Ir shell near 3.55Å almost keeps unchanged. By assuming this Ir-Ir shell distance ($d_{Ir-Ir}$) remains constant, the a-axis length is calculated. The values of a, c and d have a relationship in solid geometry: $c^2 + 2a^2 = 4d_{Ir-Ir}^2$.

**Supplementary Note S3. Discussion on simulation by Diamond**

To understand the effect of c-axis length reduction on the crystal structure of IrO$_2$, estimation is conducted with help of Diamond software. As presented in Figure 4c, d, the peaks around 3.8 Å, reflecting corner-sharing Ir-Ir shells, show negligible distance change. The distance of corner-sharing Ir-Ir atoms is a function of only c and a values. So the corner-sharing Ir-Ir distance of the composites are assumed to be same as like IrO$_2$. In this way, with a given value of c, the a-axis length can be calculated. The c-axis lengths of the composites are calibrated with the first Ir-Ir distance values in EXAFS and crystal parameters of IrO$_2$. Based on these, the values of c, a, Ir-Ir distance and Ir-O distance are estimated, as listed in Table S5. In comparison with IrO$_2$, the composite possessed two elongated polar Ir-O bonds, and four shortened planar Ir-O bonds (Table S5, values taken from Diamond simulation). The results conform the z-extension Jahn-Teller distortion. The corresponding powder patterns in Diamond clearly show the same trend in diffraction angle shift of (101) and (211) as has been observed in XRD.
