According to the widely accepted mechanism of n-alkane isomerization\(^1\), a linear alkene is initially formed on the metal sites. Subsequently, the olefinic intermediate undergoes protonation and skeletal rearrangement on the acid sites. Finally, iso-alkene is hydrogenated on the metal sites to generate a branched alkane. Based on the bifunctional hydroisomerization mechanism, via pseudo-steady-state treatment with the assumption that olefinic intermediates isomerization was the rate-limiting step\(^2, 3\).

The rate equation could be written as:

\[
\frac{r_{\text{isom}}}{[H^+]_0} = \frac{k_{\text{isom}} K_{\text{prot}} K_{\text{dehy}} nC_{12}}{1 + K_{\text{prot}} K_{\text{dehy}} nC_{12} H_2} = k_{\text{isom}} K_{\text{prot}} K_{\text{dehy}} nC_{12} H_2 \]

where \( K_{\text{dehy}} \) was the equilibrium constant for dehydrogenation of n-dodecane over Pt sites; \( K_{\text{prot}} \) were the equilibrium constant for formation of surface-bound alkoxide species by adsorption of n-dodecene on Brønsted acid sites; \( k_{\text{iso}} \) was the rate constant for isomerization of alkoxide species; \([H^+]_0\) was the number of Brønsted acid sites; \([nC_{12}]\) was the partial pressure of n-dodecane and \([H_2]\) was the partial pressure of hydrogen.

Eq. (1) could be written in a linear form as Eq. (2):

\[
\frac{[H^+]_0}{r_{\text{isom}}} = k_{\text{isom}} K_{\text{prot}} K_{\text{dehy}} nC_{12} H_2 + \frac{1}{k_{\text{isom}}} \]

The values of the apparent rate constant, \( k_{\text{app}} \), could be obtained from the values of the slope. \( k_{\text{app}} = k_{\text{iso}} K_{\text{prot}} K_{\text{dehy}} \)^2

Figure S6 shows the measured site-time yield of iso-dodecane as a function of n-C\(_{12}\)/H\(_2\) molar ratio over different catalysts. Figure S7 shows reciprocal rates of iso-
dodecane as a function of H₂/n-C₁₂ molar ratio. Figure S8 exhibits the Arrhenius plots for measured apparent rate constants.

Reaction conditions: $\text{H}_2/\text{n-dodecane} = 750$, $\text{LHSV} = 1.2 \, \text{h}^{-1}$, $P = 4.0 \, \text{MPa}$.

**DFT calculation**

It is well known that the catalytic activity of zeolites is mainly attributed to the acid strength of acid sites, which can be measured computationally by deprotonation energy (DPE). To compare the acidity of Al-ZSM-22, B-ZSM-22 and silanol nest-ZSM-22, DPE was used to measure acid strength due to DPE represents intrinsic acid strength of acid sites and is suitable in general cases. The calculations for DPEs were carried out with a two-layer ONIOM$^4$ scheme, and the quantum mechanics using B3LYP functional$^5$ was used as default for the QM calculations. An active inner layer, which includes a 5T cluster of the active site of zeolite, was treated using the 6-31+G(d,p) basis sets; the rest of the outer region was treated using UFF. So we denote data calculated using this method as ONIOM2(B3LYP/6-31+G(d,p):UFF), which is implement in Gaussian 09 program package.$^6$
In the present work, three zeolite framework structures (Al-ZSM-22, B-ZSM-22 and silanol nest-ZSM-22) were chosen to investigate the effects of different acid sites including acidic silanol and bridging hydroxyl groups (Si-OH-Al and Si-OH-B). As shown in Figure S10, a cluster model with 72 tetrahedral sites (T-sites) was built, which consists of Al or B atom surrounded by four oxygen atoms with a hydrogen atom to balance the Brønsted acid generated at the substituted T sites. B, Al and silanol defects were placed in the T2 position, which is most stable substituted T-sites according to our previous study\(^7\). The deprotonation energy (\(E_{\text{DP}}\)) was calculated from Eq. (4):

\[
\text{ZOH} \rightarrow \text{ZO}^- + \text{H}^+ \quad \quad (3)
\]

\[
E_{\text{DP}} = E(\text{ZO}^-) - E(\text{H}^+) \quad \quad (4)
\]

where ZO- and ZOH represent the deprotonated and the neutral zeolites, respectively.

Figure S10 (a) the supercell structure of TON (ZSM-22); (b) the cluster model for QM/MM calculation: the yellow, red, white sphere stands for Si, O, H atom, respectively. The central T site can be substituted for B or Al atom. In addition, the silanol defect was built by deleting the Si atom at T\(_2\) site.
