**MoS\(_2\) growth:**

Monolayer MoS\(_2\) flakes were grown directly on a 300 nm SiO\(_2\)/Si substrate by CVD. First, a 1% sodium cholate solution, known to act as a growth promoter for MoS\(_2\), is spin-coated at 4000 rpm for 60 s onto the SiO\(_2\) substrate. A droplet of a saturated solution of ammonium heptamolybdate in deionized (DI) water is deposited onto the substrate, providing the molybdenum feedstock. The substrate is placed in the center of a 1 in. CVD tube furnace and 15 mg of solid sulphur is placed 15 cm upstream from the substrate. Growth occurs at an atmospheric pressure in a flow of 750 sccm of nitrogen gas (99.999% purity). The furnace temperature is ramped to 750 °C at a rate of 70 °C min\(^{-1}\). While the Mo source and SiO\(_2\) growth substrate reach 750 °C, the maximum temperature of the sulphur is \(\sim 150 \degree C\). After a 15 min growth period, the furnace is opened, and the sample is rapidly cooled to room temperature in 1000 sccm flowing nitrogen.

**MoS\(_2\) transfer:**

The transfer of MoS\(_2\) to the GC substrates was accomplished by spin-coating PMMA onto the as-grown sample, which was then placed in a bath of 0.1 M KOH to slowly etch the SiO\(_2\) surface and release the PMMA/MoS\(_2\) layer from the substrate. The floating PMMA/MoS\(_2\) layer was then transferred into successive water baths for cleaning and finally scooped onto a target substrate. The sample was then dried, and the PMMA was removed with an acetone spray, followed by an acetone bath.

**Ion irradiation:**

Swift Heavy Ion (SHI) irradiation was performed at the IRRSUD beamline of the GANIL facility in Caen, France. \(^{129}\)Xe\(^{+23}\) ions with a kinetic energy of 0.71 MeV/u were used. The calibration of the angle of incidence was performed as follows: First, a telescope was mounted on the optical axis of the beamline. The position at which the surface of the sample is parallel to the optical axis was determined as zero degrees. Second, a SrTiO\(_3\) sample was irradiated under a non-zero angle with a fixed fluence (ions/\(\mu\)m\(^2\)). Analysis with AFM afterwards allows us to determine the density of ion impacts on the SrTiO\(_3\) surface (defect creation efficiency of SHI in SrTiO\(_3\) is one). As the density of ion impacts scales with sin\(\theta\) (in which \(\theta\) is the angle of incidence with respect to the surface), we can compare the experimentally determined angle of incidence with the chosen one and calibrate the setup.

**Raman- and photoluminescence analysis:**

Fig. S1 compares Raman- and photoluminescence (PL) measurements of SHI irradiated CVD grown single-layer MoS\(_2\). The results are presented as a single point measurement in S1 (a) and as mappings in S1 (b)-(e). Fig. S1 (a) gives an impression of the crystallinity of the MoS\(_2\) flakes prior and after irradiation taking the amount of photoluminescence of the MoS\(_2\) after laser excitation as a measure for the degree of crystallinity. Comparing the intensity of the typical Raman active A\(_{1g}\) and E\(^{12g}\) in MoS\(_2\) (\(\sim 385\) cm\(^{-1}\) and 404 cm\(^{-1}\)) with the PL peak (\(\sim 3900\) cm\(^{-1}\)) the MoS\(_2\) shows high crystallinity prior to irradiation (black curve). After irradiation one can still clearly observe both the Raman modes as well as a PL peak, however, due to ion irradiation and defect creation, the crystallinity of the MoS\(_2\) has obviously degraded.

Fig. S1 (b)-(c) presents PL mappings of non-irradiated (b) and irradiated (c) MoS\(_2\). As expected, non-irradiated MoS\(_2\) shows a homogeneous PL over the whole sample. Irradiated MoS\(_2\) in contrast shows a rather inhomogeneous PL signal over the MoS\(_2\) samples, which can be attributed to the ripping and tearing of the MoS\(_2\) caused by ion impact, as shown in the SEM in the manuscript in Fig. 2. A similar
behavior can be observed when analyzing the distance of the Raman active $A_{1g}$ and $E_{12g}$ modes in Fig. S1 (d)-(e). Pristine MoS$_2$ in Fig. S1 (d) shows a Raman mode difference of ~ 21 cm$^{-1}$ evenly distributed over the sample. Irradiated MoS$_2$ however, shows a varying mode difference. It has been shown that a varying distance of the $A_{1g}$ and $E_{12g}$ mode can be explained by a locally varying degree of strain and/or doping in the MoS$_2$.\textsuperscript{1,2} Considering the 3D Origami-like foldings of the MoS$_2$ (see Fig. 2 in manuscript) SHI impacts under grazing incidence are likely to induce also strain in the MoS$_2$, aside from foldings and incisions. Also, due to the adsorption of oxygen at the under-coordinated Mo edges, it is likely that the MoS$_2$ will experience a p-doping, which also causes an increase in the distance of the Raman modes.\textsuperscript{3,4}

Figure S1: (a) Point measurement of non-irradiated (black curve) and irradiated (red curve) showing MoS$_2$ Raman active modes and PL peak. Mappings of PL peak intensity of non-irradiated (b) and irradiated MoS$_2$ (c). The intensity of the PL mappings is each normalized. Mapping of the distance of $A_{1g}$ and $E_{12g}$ modes in (d) and (e) showing differences of 17 cm$^{-1}$ and 24 cm$^{-1}$. 
the Raman active $A_{1g}$ and $E_{12g}^{1}$ modes of pristine (d) and irradiated MoS$_2$ (e). Measurements were performed with a 532 nm laser. Ion fluence for the irradiated samples was chosen to 2300 ions/µm$^2$.

**SEM analysis:**

SEM images of irradiated (Fig. S2 (a)) and non-irradiated (Fig. S2 (b)) MoS$_2$/glassy carbon surfaces demonstrate the morphological changes induced by SHI irradiation. While the pristine MoS$_2$ on glassy carbon shows no structural irregularities, one can clearly observe incisions in the MoS$_2$ both on SiO$_2$ (Fig. 2 in manuscript) and on glassy carbon (Fig. 2 (d) in manuscript and Fig. S2 (a)) substrates after ion irradiation.

![Figure S2. SEM images of (a) ion-irradiated MoS$_2$ on glassy carbon, and (b) of a non-irradiated, nominally identical sample. The irradiation-induced incisions are visible in (a) (elongated features extending from left to right, examples shown in ovals). The length scale in (a) corresponds to 2 µm (magnification factor 20000), in (b) to 5 µm (magnification factor 10000).](image)

Fig. S3 presents additional SEM images of irradiated (a) and non-irradiated (b) MoS$_2$/glassy carbon samples. The 3D structures (white details in circles) are only present in the irradiated samples and moreover only in the MoS$_2$ covered part. Bare glassy carbon areas (lower right part in (a)) show no such structures. Non-irradiated samples (Fig. S3 (b)) show no such features, neither on the MoS$_2$ covered parts nor on the glassy carbon parts.

![Fig. S3 presents additional SEM images of irradiated (a) and non-irradiated (b) MoS$_2$/glassy carbon samples.](image)
Figure S3. SEM images of (a) ion-irradiated MoS$_2$ on glassy carbon, and (b) of a non-irradiated, nominally identical sample. The 3D structures are clearly visible on the MoS$_2$ covered part of the sample in (a), with examples highlighted within circles. The glassy carbon substrate (lower right part of (a) is not significantly affected by the irradiation and exhibits no 3D structures. The length scale corresponds to 2 $\mu$m (magnification factor 20000).

XPS of (non-) irradiated MoS$_2$:

Additional XPS data of non-irradiated and irradiated MoS$_2$ on Si/SiO$_2$ substrates are given in Fig. S4. Again, we compared XPS spectra of non-irradiated (Fig. 4 (a)) and irradiated (Fig. S4 (b)) MoS$_2$ on SiO$_2$/Si substrates. In analogy to Fig. 5, we witnessed a strong decrease of the S concentration. Comparing the intensity of the S 2p peaks with the Si 2s, we see a clear decrease in the amount of S. While the non-irradiated sample showed an intensity ratio of $I_{2pS}/I_{2pSi} \approx 0.21$, the irradiated one showed a ratio of just 0.13.

Note that for the intensity ratios of Mo/S only relative and no absolute values are calculated, therefore no RSF were taken into consideration.

Figure S4: XPS spectra of non-irradiated (a) and irradiated (b) MoS$_2$ on SiO$_2$/Si substrates. Comparing the intensity ratios $I_{2pS}/I_{2pSi}$ prior and after irradiation, we observe a strong decrease from $\sim 0.22$ down to just 0.13. Measurements were performed with a PHI 5000 Versaprobe II under room temperature.
Two Temperature Model and Molecular Dynamics:

We simulate the SHI irradiation with the two-temperature model (TTM) formalism.\(^5,6\) This model describes the evolution of the electronic and lattice subsystems with two differential equations coupled with an energy exchange term

\[
\begin{align*}
\frac{\partial T_e}{\partial t} &= \nabla (K_e \cdot \nabla T_e) - g(T_e - T_l) + A(r,t) \\
\frac{\partial T_l}{\partial t} &= \nabla (K_l \cdot \nabla T_l) + g(T_e - T_l)
\end{align*}
\]

, where \(K\) denotes the thermal conductivity, \(C\) the heat capacity, \(g\) the electron-phonon coupling, \(A(r,t)\) the initial electronic energy distribution and the subscripts \(l\) and \(e\) refer to the lattice and electronic subsystems, respectively.

For the irradiation effect in \(\text{MoS}_2\) we employ in the simulations the following thermodynamical parameters \(K_l = 34.5 \text{ Wm}^{-1}\text{K}^{-1}\)\(^7,8\), \(C_l\) from Ref.\(^9\), \(K_e = D_e \cdot C_e\) obtained as in Ref.\(^10,11\) and \(g = C_e / \tau\) with \(\tau \sim 0.6 \text{ ps}\)\(^12,13\). The electronic heat capacity is calculated from the density of states\(^14\) as

\[
C_e(T_e) = \int_{-\infty}^{\infty} \frac{\partial f(E,\mu, T_e)}{\partial T_e} g(E) E dE
\]

Here we use the free electron density of states \(g(E)\) calculated with effective masses \(m_h = 0.92 m_o\), \(m_e = 0.82 m_o\)\(^15\) and energy gap \(E_g = 1.8 \text{ eV}\)\(^16\)

\[
\begin{align*}
g_c(E) &= \frac{8\pi \sqrt{2}}{h^3} \frac{3}{m_e^2} E \quad E \geq E_c \\
g_v(E) &= \frac{8\pi \sqrt{2}}{h^3} \frac{3}{m_h^2} E \quad E \leq E_v
\end{align*}
\]

We use the CasP software to obtain the initial amount of energy deposited to the electronic subsystem.\(^17\) This method calculates the energy deposited by an ion to every atom based on its impact parameter. In reality, the ions deposit the energy to the electrons locally, producing an electronic cascade, which propagates several nanometers away from the track. In order to model this mechanism, we bin the energy deposited by the ion along the trajectory in 1 nm bins, and then we redistribute the bin energy spatially perpendicular to the ion trajectory using the Waligorski distribution for electron cascades.\(^18\) We use the electronic energy distribution as initial conditions and solve the differential equations in a 2D grid of dimensions 400x400 nm\(^2\) and element size 1x1 nm\(^2\). After 1 ps, we take the lattice energy distribution in the center of the grazing impact point and deposit it to the atoms in the MD cell by adding the velocity in a random direction. We apply the Berendsen thermostat on the borders of the cell to account for the energy dissipation on the bulk.

The simulations were performed using the REBO potential for \(\text{MoS}_2\)\(^19\) with the LAMMPS software.\(^20\) The chosen potential reproduces accurately the formation energy of the Sulphur and Molybdenum vacancies,\(^21\) making it suitable for irradiation applications.

To model the increasing temperature of the \(\text{SiO}_2\) substrate after ion impact, we employed the TTM. The region, where the temperature rises above the melting temperature of the particular material, undergoes a phase transition which leads to a permanent modification of the surface after cooling. This region typically manifest itself as a rift or track in the case of grazing incidence.\(^22\) Comparing the temperature of \(\text{SiO}_2\) substrate with the sublimation temperature of \(\text{MoS}_2\) and \(S\) allows us to make qualitative assumptions whether or whether not the temperature is high enough to evaporate \(\text{MoS}_2\).
and/or S. For the calculation of the thermal spike in SiO$_2$ we used the following parameters: $g = 1.2 \times 10^{19}$ W/K m$^3$; $K_l = 1.5$ W m$^{-1}$ K$^{-1}$, $C_l = 1$ J/g K$^{-1}$; $K_e = D_e \cdot C_e$ were obtained as described in Ref. [23].

**Electrochemical analysis:**

The catalytic activity of the MoS$_2$ catalysts for the hydrogen evolution reaction (HER) was measured at room temperature using a conventional three-electrode configuration connected to a potentiostat (SP-240, Bio-Logic). The catalyst sample was employed as the working electrode, a Pt mesh as the counter electrode and an Ag/AgCl wire (in a saturated 3M KCl solution) as the reference electrode. The electrolyte used for the HER was a 0.5 M H$_2$SO$_4$ aqueous solution, which was purged with Ar gas (99.999%) for 30 min before the reaction to remove air and other residual gases. Linear sweep voltammetry (LSV) measurements were performed at a scan speed of 5 mV/s. Applied potential values versus Ag/AgCl were referenced to the reversible hydrogen electrode (RHE) by using the expression: $E_{\text{RHE}} = E_{\text{Ag/AgCl}} + 0.0591 \text{pH} + E_{\text{Ag/AgCl}}^{0}$, where $E_{\text{Ag/AgCl}}$ is the experimentally applied potential and $E_{\text{Ag/AgCl}}^{0}$ the potential difference between the Ag/AgCl electrode and the normal hydrogen electrode (NHE), which is equal to +0.210 V at room temperature. All voltammograms were corrected through iR compensation for addressing the iR drop between the working electrode and the reference electrode by measuring the solution resistance via electrochemical impedance spectroscopy.

For the linear sweep voltammetry measurements, the current density was calculated by dividing the measured catalytic current by the geometrical surface area of MoS$_2$ on the glassy carbon substrate. The surface area was determined using the Gwyddion software package$^{25}$ to analyze SEM images of the sample surface. For the analysis a Gaussian filter (pixel averaging) was first applied to homogenize the background and enhance the contrast between the uncovered substrate area and the MoS$_2$-covered regions. Automatic edge detection (by threshold) followed by subsequent manual refinement were used to precisely mark the MoS$_2$ regions. The grain property distribution provided the surface ratio of the marked regions to the surrounding background area. In this way the relative coverage was determined for each SEM image. The results obtained from various SEM images were then averaged to provide the overall coverage of the sample.

The electrode geometrical surface area was 240 mm$^2$, with a 16-18% effective MoS$_2$ surface coverage depending on the sample pre-treatment (16% on the irradiated and 18% on the non-irradiated samples).

The charge transfer resistance, that provides information on the kinetics of the electrochemical reaction, was determined in our study by electrochemical impedance spectroscopy (EIS). Fig. S5 shows the Nyquist plot of our MoS$_2$ samples and of a bare glassy carbon substrate at -0.25 V vs RHE. The left and right intersection points of the EIS semicircle with the x-axis indicate the value of the solution resistance (ohmic resistance), used to compensate the iR drop, and the sum of the solution resistance and charge transfer resistance ($R_e$), respectively. By subtracting the latter value from the former, the charge transfer resistance $R_e$ was determined. A smaller value of $R_e$ means faster electric charge transfer between the catalyst and the reactive species. As seen in Fig. S5, the irradiated MoS$_2$ sample exhibits a lower charge transfer resistance ($R_{ct, \text{irr}} = 3189 \, \Omega$), thus faster kinetics, compared to the non-irradiated sample ($R_{ct, \text{non-irr}} = 3617 \, \Omega$).
Figure S5. Nyquist plot of irradiated (blue) and non-irradiated (red) MoS$_2$ samples on glassy carbon, as well as of a bare glassy carbon (GC) substrate (black). The EIS experiments carried out in the frequency range of 1 MHz to 0.1 Hz at -0.25 V vs RHE. The inset shows the high-frequency region of the plot, used for determining the solution resistance.
