Experimental Section

**Materials:** All materials for the active layer were purchased from Solarmer, Inc (Beijing) and used as received.

**Device fabrication:** The patterned indium-tin-oxide (ITO) coated glass substrates (10 Ω per square) were cleaned sequentially in detergent, de-ionized and ethanol by sonication and then blow-dried by high-purity nitrogen. All pre-cleaned ITO substrates were treated by UV-ozone for 15 minutes. Subsequently, poly(3,4-ethylenedioxythiophene):poly (styrene sulfonate) solution was spin-coated on ITO substrates at 4000 rpm for 30 s and annealed at 160 °C for 10 min in air. Then the PEDOT:PSS coated ITO substrates were transferred into a nitrogen-purged glove box. The solutions used for solar cell active layers were prepared by dissolving PTB7-Th:IEICO-4F, PBDB-T:ITCC and PTB7-Th:PC_{71}BM (D:A ratio = 1:1.5, 1:1 and 1:1.5w/w, respectively) in chlorobenzene (CB) at a polymer weight concentration of 15 mg/ml, 10 mg/ml, and 12 mg/ml, respectively with using 1,8-iodooctane (DIO) as solvent additives. The active layers were casted from these BHJ solutions atop PEDOT:PSS and thermally annealed at 100 °C for 10 min. After that, 5 nm of PFN-Br was spun-coat atop the BHJ films as the electron transporting layer. Finally, 80 nm of Al cathode was thermally evaporated onto PFN-Br under high vacuum, yielding an effective device area of 4.0 mm².

**Characterization:** Current-voltage (J-V) characteristics of solar cells were measured in a high-purity nitrogen-filled glove box using a Keithley 2400 source meter under AM 1.5G irradiation (100 mW/cm²) provided by an XES-70S1 (SANYOU Electric Co., Ltd.)
solar simulator (AAA grade, 70mm×70mm photobeam size) and calibrated by a standard silicon reference cell. The external quantum efficiency (EQE) spectra of solar cells were measured by a Solar Cell Spectral Response Measurement System QE-R3011 (Enli Technology Co. Ltd., Taiwan). Ultraviolet-visible (UV-Vis) absorption spectra of neat and blend films were obtained using a Shimadzu UV-3101 PC spectrometer. Irradiation-dependent solar cell testing was performed by applying a filter wheel with customized optical densities between the samples and light source to obtain desired illumination intensities. Single-carrier devices were fabricated based on the same active layers used for solar cells but different electrodes and interlayers. The hole-only and electron-only devices were in a configuration of ITO/PEDOT:PSS/active layer/Au and ITO/ZnO/active layer/PFN-Br/Al, respectively. Double-carrier devices adopted with the same structure as solar cell devices (ITO/PEDOT:PSS/active layer/PFN-Br). Dark J-V curves characteristics of all carrier devices were measured under dark conditions using a Keithley 4200 semiconductor parameter analyzer. The mobility of hole, electron and double carriers were calculated by fittings using Mott-Gurney law. The reduction factor $\gamma$ was quantified based on the extracted mobilities, according to the relation,

$$\gamma = \frac{16\pi}{9} \frac{\mu_h \mu_e}{\mu_{\text{double}}^2 - (\mu_h + \mu_e)^2}$$

where $\mu_{\text{double}}$ is the effective mobility of double carriers in the solar cell, and $\mu_h$, $\mu_e$ are the mobility of holes and electrons carriers, respective. Impedance analysis of solar cells was carried out under different light intensities by using an electrochemical workstation. The impedance data were fitted by using the ZView program. TPC
measurements were performed by a customized transient measurement systems (Physike Technology Co., Ltd) with using a pulsed semiconductor laser (Coherent, Inc.)

GIWAXS measurements were performed on a Xenocs Xeuss SAXS/WAXS beamline system. Atomic force microscopy (AFM) images were acquired on a Multimode 8 HR (Bruker, Inc.) microscope system in the tapping mode.
