Experimental

Materials: Sodium gluconate (C₆H₁₁NaO₇, 99.0%), sodium carbonate (Na₂CO₃, 99.0%), hydrochloric acid (HCl, 99.0%), and ethanol (C₂H₆O, 99.0%), ammonium chloride (NH₄Cl), salicylic acid (C₇H₆O₃), sodium citrate dehydrate (C₆H₅Na₃O₇·2H₂O), p-dimethylaminobenzaldehyde (C₉H₁₁NO), sodium nitroferricyanide dihydrate (C₅FeN₆Na₂O·2H₂O), benzyl disulfide (BDS), sodium hypochlorite solution (NaClO) and graphene oxide (GO) powder were purchased from Aladdin Ltd. (Shanghai, China). Nafion (5 wt%) solution was purchased from Sigma-Aldrich Chemical Reagent Co., Ltd. Hydrochloric acid, nitric acid, sulfuric acid, hydrogen peroxide, hydrazine monohydrate (N₂H₄·H₂O) and ethyl alcohol (C₂H₅OH) were purchased from Beijing Chemical Corp. (China). chemical Ltd. in Chengdu. The ultrapure water used throughout all experiments was purified through a Millipore system. All reagents were analytical reagent grade without further purification.

Preparation of S-G and G: S-graphene was synthesized by directly annealing GO and BDS in argon. The anneal treatment was carried out in a tube furnace with high purity argon as protective ambient. The detailed procedure is as follows. GO and BDS with mass ratio of GO and BDS of 1:2 was ultrasonically dispersed in ethanol for about 30 min. The resulting suspension was spread onto an evaporating dish and dried, forming a uniform solid mixture. The mixture was placed into a quartz tube with argon atmosphere and annealed at 1050 °C. After that, the sample was cooled to room temperature under ambient Ar and collected from the quartz tube. For comparison, undoped G was prepared GO without BDS was treated under the same condition.

Characterizations: Transmission electron microscopy (TEM) images were collected on a HITACHI H-8100 electron microscopy (Hitachi, Tokyo, Japan) operated at 200 kV. XPS measurements were performed on an ESCALABMK II X-ray photoelectron spectrometer using Mg as the exciting source. Raman spectra were obtained by a Renishaw inVia confocal
Raman microprobe under 532 nm laser excitation. The absorbance data of spectrophotometer were acquired on SHIMADZU UV-1800 UV-Vis spectrophotometer.

**Electrochemical Measurements:** Electrochemical NRR measurements were performed in a two-compartment cell separated by Nafion membrane using a CHI660E electrochemical analyzer (CH Instruments, Inc.). The electrochemical experiments were carried out with a three-electrode configuration using graphite plate as the counter electrode and Ag/AgCl/saturated KCl as the reference electrode. The working electrode was a modified. In a typical synthesis of electrode, 10 mg of the catalyst was dispersed in 1 mL of water containing Nafion solution (5 wt%), followed by ultrasonic treatment for 30 min to form a homogeneous ink. Then, 10 μL of the ink was loaded onto a carbon paper electrode with area of 1 x 1 cm$^2$ and dried under ambient condition, the catalyst loading mass is 0.1 mg. The potentials reported in this work were converted to reversible hydrogen electrode (RHE) scale via calibration with the following equation: $E \text{ (vs. RHE)} = E \text{ (vs. Ag/AgCl)} + 0.256 \text{ V}$ and the presented current density was normalized to the geometric surface area. For electrochemical N$_2$ reduction, chrono-amperometry tests were conducted in N$_2$-saturated 0.1 M HCl solution (the HCl electrolyte was purged with N$_2$ for 30 min before the measurement).

**Determination of NH$_3$:** Concentration of produced NH$_3$ was spectrophotometrically determined by the indophenol blue method. Typically, 2 mL electrolyte was taken from the cathodic chamber, and then 2 mL of 1 M NaOH solution containing 5% salicylic acid and 5% sodium citrate was added into this solution. Subsequently, 1 mL of 0.05 M NaClO and 0.2 mL of 1% C$_5$FeN$_6$Na$_2$O$_2$H$_2$O were add into the above solution. After standing at room temperature for 2 h, the UV-Vis absorption spectrum was measured at a wavelength of 655 nm. The concentration-absorbance curves were calibrated using standard NH$_3$ solution with a serious of concentrations. The fitting curve ($y = 0.3713x + 0.0515$, $R^2 = 0.999$) shows good linear relation of absorbance value with NH$_3$ concentration by three times independent calibrations.
Determination of $\text{N}_2\text{H}_4$: The $\text{N}_2\text{H}_4$ presented in the electrolyte was estimated by the method of Watt and Chrisp.\textsuperscript{2} A mixed solution of 5.99 g C$_9$H$_{11}$NO, 30 mL HCl and 300 ml ethanol was used as a color reagent. Calibration curve was plotted as follow: firstly, preparing a series of reference solutions; secondly, adding 5 mL above prepared color reagent and stirring 20 min at room temperature; finally, the absorbance of the resulting solution was measured at 455 nm, and the yields of $\text{N}_2\text{H}_4$ were estimated from a standard curve using 5 mL residual electrolyte and 5 mL color reagent. Absolute calibration of this method was achieved using $\text{N}_2\text{H}_4\cdot\text{H}_2\text{O}$ solutions of known concentration as standards, and the fitting curve shows good linear relation of absorbance with $\text{N}_2\text{H}_4\cdot\text{H}_2\text{O}$ concentration ($y = 1.0734x + 0.0318$, $R^2 = 0.999$) by three times independent calibrations.

Calculations of $\text{NH}_3$ formation rate and FE: The FE for $\text{N}_2$ reduction was defined as the amount of electric charge used for synthesizing $\text{NH}_3$ divided the total charge passed through the electrodes during the electrolysis. The total amount of $\text{NH}_3$ produced was measured using colorimetric methods. Assuming three electrons were needed to produce one $\text{NH}_3$ molecule, the FE could be calculated as follows:

Ammonia formation was calculated using the following equation:

$$\text{Ammonia formation rate} = [\text{NH}_4^+] \times \frac{V}{(m \times t)}$$

FE was calculated according to following equation:

$$\text{FE} = 3 \times F \times [\text{NH}_4^+] \times \frac{V}{(17 \times Q)}$$

Where $[\text{NH}_4^+]$ is the measured $\text{NH}_4^+$ ion concentration; $V$ is the volume of the cathodic reaction electrolyte; $t$ is the potential applied time; $m$ is the loaded quality of catalyst; $F$ is the Faraday constant; and $Q$ is the quantity of applied electricity.

Computational method: All electron spin-polarized DFT methods implemented in the DMol3 module of Material Studio package have been employed for all present calculations.\textsuperscript{3,4} The generalized gradient approximation Perdew-Burke-Ernzerhof (PBE) exchange-correlation functional is adopted.\textsuperscript{5} The van der Waals interaction is described using the empirical
correction scheme of Grimme.\textsuperscript{6} To expand the electronic wavefunction, the double numerical plus polarization (DNP) basis set is used.\textsuperscript{7} Self-consistent field (SCF) calculations are performed with a total energy convergence criterion of $10^{-6}$ hartree. Since bulk water layer slightly stabilizes NRR intermediates,\textsuperscript{8} we have therefore adopted the conductor-like screening model (COSMO) to implicitly consider solvent effects.\textsuperscript{9}

Twelve sulfur-doped models have been constructed in our work. Eight of them are sulfur-doped graphene models. For them, a $6 \times 6$ two-dimensional graphene supercell has been used. In DFT calculations, a $5 \times 5 \times 1$ Monkhorst–Pack k-points are used. However, for the S-doped graphene nanoribbon models, both $4 \times 5$ zigzag and $9 \times 3$ armchair graphene nanoribbons are employed in which a $1 \times 1 \times 5$ Monkhorst–Pack k-points are used in the DFT calculations. In both situations, to avoid artificial interaction a more than 15 Å vacuum layer is used between two neighboring slabs. Fig. S9 schematically illustrates our constructed sulfur-doped graphene models.

Six net proton coupled electron transfer (PCET) steps are involved in NRR processes ($\text{N}_2 + 6\text{H}^+ + 6\text{e}^- \rightarrow \text{NH}_3$). According to previous theoretical studies,\textsuperscript{10} gaseous $\text{H}_2$ is employed as the proton source due to its convenience of simulating the anode reaction i.e. $\text{H}_2 \leftrightarrow 2(\text{H}^+ + \text{e}^-)$. Every PCET step involves the transfer of a proton coupled with an electron from solution to an adsorbed species on the surface of electrocatalyst. The Gibbs free energy change ($\Delta G$) of every elemental step is calculated by using the standard hydrogen electrode (SHE) model proposed by Nørskov et al.,\textsuperscript{11-13} which uses a half of chemical potential of hydrogen molecule as the chemical potential of a proton-electron pair. In detail, the free energy change is defined: $\Delta G = \Delta E + \Delta ZPE - T\Delta S + \Delta G_{\text{pH}} + \Delta G_U$, where $\Delta E$ is the reaction energy directly obtained from DFT calculations; $\Delta ZPE$ is the change in zero-point energy; $T$ is temperature (298.15 K); and $\Delta S$ is the change in entropy. $\Delta G_U = -n_e U$, where $n$ is the number of electrons transferred and $U$ is the electrode potential. $\Delta G_{\text{pH}}$ is the correction of the $\text{H}^+$ free energy by the concentration, determined as $\Delta G_{\text{pH}} = 2.303 \times k_B T \times \text{pH}$ (or 0.059 $\times$ pH), where $k_B$ is the
Boltzmann constant and the value of pH is assumed to be zero. The zero-point energies and entropies of the NRR species are determined from the vibrational frequencies in which only the adsorbed species’ vibrational modes are computed explicitly and the electrocatalyst sheet is fixed. The entropies and vibrational frequencies of gas phase molecules are taken from the NIST database [http://cccbdb.nist.gov/].

We have calculated the adsorption energy of the N\textsubscript{2} and NNH species on the catalyst sheet. The adsorption energy of X species \( E_{\text{ads}}(X) \) is calculated as the energy difference

\[
E_{\text{ads}}(X) = - [ E(\text{total}) - E(\text{surface}) - E(X) ]
\]

where \( E(\text{surface}) \), \( E(X) \), and \( E(\text{total}) \) are the potential energies of the clean surface, gas-phase X species, and the adsorbed X species, respectively.
