Section S1: Materials

Gallic acid (GA), sodium hydroxide (NaOH), lithium perchlorate (LiClO₄, 95.0%), and acetonitrile (99.5% ACN) were purchased from Sigma-Aldrich and used as received. Gallium ingots were purchased from Rotometals, Inc. Green tea bag (GT, Twinings) and cocoa nibs (Cacao Nibs, Macro) were purchased from a local market. High-purity (Milli-Q) H₂O with a resistivity of 18.2 MΩ.cm was obtained from an inline Millipore RiOs/Origin H₂O purification system.

Section S2: Characterisation

Scanning electron microscopy (SEM) images were obtained using a Nova Nano SEM 450 at an accelerating voltage of 10 kV. Energy-dispersive X-ray spectroscopy (EDS) mapping were obtained using a Nova Nano SEM 450 at an accelerating voltage of 20 kV. GA/Ga embedded paper samples sputtered with carbon coating were used for EDS analyses. Fourier transform infrared (FTIR) spectra were obtained using an attenuated total reflectance (ATR-FTIR) spectrometer (PerkinElmer). UV-Vis absorption spectra were recorded on a Cary 5000 (PerkinElmer) spectrophotometer. Transmission electron microscopy (TEM) images were obtained by high-resolution TEM (Phillips CM200, Amsterdam, Netherlands). X-ray photoelectron spectroscopy (XPS) was performed on an ESCALAB250Xi spectrometer (Thermo Scientific, UK). The incident radiation was monochromatic Al Kα X-rays (1486.68 eV) at 120W (13.8 kV × 8.7 mA). Survey (wide) and high resolution (narrow) scans were taken at analyser pass energies of 100 eV and 20 eV, respectively. Base pressure in the analysis chamber was below 2.0 × 10⁻⁹ mbar. All data were processed using Advantage software and the energy calibration was referenced to the C 1s peak at 284.8 eV.

Electrical and electrochemical characterisation: The conductivity was calculated based on the resistance value obtained by the measurements through a two-probe technique using a digital multimeter (model Siglet SDM3065X). The equation for this calculation is as follows:

\[ \sigma = \frac{L}{RA} \]  

where \( L \) is the distance in between the probes, \( A \) is the transversal area and \( R \) is the resistance in Ω. Electrochemical assays were conducted to characterise the performance of the conductive paper as an electrode in the capacitor prototype. Cyclic voltammetry (CV) was carried out to assess the voltage window where a quasi-rectangular shape is obtained for the capacitor, considering different operational scan rates and define the current density limits applicable to
the charge-discharge assays. CV of the control paper sample (i.e., without GA/Ga) was also
conducted with a scan rate of 200 mV/s using 0.1M LiClO₄ in ACN as electrolyte solution.

Galvanostatic charge-discharge (GCD) cycles were obtained using different currents detailed
in the text. GCD curves were also employed to evaluate the specific capacitance, \( SC \), according
to:

\[
SC = \frac{\int I \cdot dt}{\Delta V \cdot m_{Ga}}
\]

where \( I \) is the applied current, \( \Delta t \) is the time (s) of charge or discharge, \( \Delta V \) is the difference
between the potential (V) at the beginning and at the end of the charge or discharge, which in
this case was fixed as 1 V and \( m \) is the mass (g) of Ga contained in the cellulose paper. The
capacitance retention was analysed by GCD after 100 cycles applying 0.50 mA/g.

Electrochemical impedance spectroscopy (EIS) diagrams were taken at open–circuit cell
potential (OCP) that is P over the frequency range of 100 kHz to 10 Hz. All experiments were
performed using an CHI600e and CHI660e potentiostat/galvanostat workstation, at room
temperature using 0.1M LiClO₄/ACN as the electrolyte solution.

Section S3: Synthesis of GA/Ga dispersion

In a typical synthesis, 20 µL of liquid Ga (preheated at 60 °C on a hotplate) was added to a
glass vial containing GA solution (2 mg mL⁻¹, 10 mL, pH adjusted to 6 by 1M NaOH, preheated
at 60 °C on a hotplate). The vial was sealed and sonicated in a bath sonicator for 60 min and
the bath temperature was maintained around 60 °C during sonication. After sonication the vial
was taken out and left at room temperature for 2 min to allow the large particles to be settled
down at the bottom of the vial. 1 mL of the supernatant suspension was taken out and washed
3 times in Milli-Q water via centrifugation (mini Spin plus, 8000 rpm, 2 min) to discard the
excess reactants. The obtained particles were finally re-dispersed in Milli-Q water and this
dispersion was used for further characterisation. Control experiments were also performed in
Milli-Q water (without GA) in identical conditions as above. GA/Ga dispersions were also
prepared with GA concentration of 0.5 and 5 mg mL⁻¹ in identical manner as above.

Section S4: Synthesis of GT/Ga dispersion

Boiling water was used for preparing the GT stock solution, briefly, 2 teabags were soaked in
the boiling water (~100 mL) for 3 min and the teabags were taken out. The resulting extract
was cooled to room temperature and filtered through a 0.45 µm membrane filter to discard
large particles. The resulting filtrate (GT stock solution) was employed to prepare the GT/Ga dispersion, the process of which is identical to the process of GA/Ga dispersion as described in Section S3.

Section S5: Synthesis of Cocoa/Ga dispersion

Boiling water was used for preparing the Cocoa stock solution. Briefly, 2 g of cocoa nibs was grinded with the aid of a mortar; the resulting powder was dispersed in boiling water and sonicated in a bath sonicator for 15 min. The resulting extract was cooled to room temperature and filtered through a 0.45 µm membrane filter to separate and discard large particles. The resulting filtrate (Cocoa stock solution) was utilised to prepare the Cocoa/Ga dispersion, the process of which was identical to the process of GA/Ga dispersion as described in Section S3.

Section S6: Impregnation of GA/Ga dispersion into paper membranes

The GA/Ga dispersion was prepared in identical conditions as described in Section S3. After sonication, the dispersion (10 mL) was washed 3 times in water via centrifugation and finally re-dispersed in 4 mL of water. 100 µL drop of the final dispersion was spread over a commercial filter paper cut into the size of 2 cm × 7 cm (Whatman, pore size ~11 µm, thickness of 0.2 mm). The last step was repeated until the entire dispersion was used up. The dimension of the paper was chosen to match the dispersion volume required to completely fill up the membrane matrix. Note that unlike Section S3, the large particles were not separated in this case. For quick evaporation of water, while spreading the drop, the paper sample was kept at 70 °C using a hot plate. After complete impregnation of the paper by GA/Ga particles, the composite paper was washed in Milli-Q water to remove loosely bound particles and dried. The dried composite paper was then sandwiched between two polypropylene sheet (thickness of 0.4 mm) and mechanically pressed by a press-rolling system (gap between rod 0.9 mm) to fuse the particles together in a matrix.

Section S7: Preparation of paper samples for electrochemical tests

GA/Ga impregnated paper samples after fusion (as obtained from Section S6) were cut into 4 mm × 6 mm size and placed onto the surface of copper sheets of 4 mm × 20 mm size. The joint was glued using Kapton® tape. The distance between the plates was 5 mm. The electrolyte used was 0.1 M LiClO₄/acetonitrile (ACN). A closed system was designed to avoid the ACN evaporation. The electrolyte solution was bubbled with N₂ for 10 min before each assay to remove the dissolved oxygen and prevent further oxidation of the electrodes.

with a scan rate of 200 mV/s. (c) Analysis of electroactivity of the composite paper by GCD plot during the first 100 cycles by applying 0.50 mA/g.

**Figure S15.** GCD plot of specific capacity vs potential for the composite paper after fusion, the best performance achieved at 0.28 mA/g in the potential window from -0.50 to 0.50 V.

**Figure S16.** EIS assays for the GA/Ga embedded conductive paper membranes: (a) Nyquist plot with an inset corresponding to the amplified area of the low frequency zone for better visualisation and Bode plots (b, c) of the composite paper-based capacitor.

It is evident from the EIS assays that a diffusion-limited process drives the kinetics of the capacitor. The Nyquist and Bode plots are displayed in Figure S16. A straight line was observed in the Nyquist plot (Figure S16a) which is consistent with the trend of a typical electrical double-layer of porous capacitors. The inset (Figure S16a) shows that at high frequencies, the
The semicircle characteristic of the charge transfer resistance was absent, meaning that our process was improved by the porous structure of the cellulose paper electrode and possibly the presence of GA adduct released after shell rupture during fusion, which favoured the permeation of the electrolyte and enhances the ion transfer kinetics. The shapes of the Bode plots as shown in Figure S16 (b, c) are typical of conducting materials. However, the linear trend observed around $2 \times 10^2 \text{ Hz}$ at the centre of the Bode-phase plot indicates a diffusion limited process at the electrode-electrolyte interface that agrees well with the trend observed for the Nyquist plot.
