Experimental section

Synthesis of hematite nanowires

Hematite (α-Fe₂O₃) nanowires were grown on a fluorine-doped tin oxide (FTO) substrate according to a previously reported method. A Teflon-lined stainless steel autoclave was filled with 20 ml aqueous solution containing 0.15 M of ferric chloride (FeCl₃·6H₂O, Acros 99+%) and 1 M sodium nitrate (NaNO₃, Fisher 99.4%). The solution pH was adjusted to 1.5 by adding HCl solution. A FTO substrate pre-cleaned with acetone, ethanol and distilled water was put into the autoclave. The autoclave was heated at 95 °C for 4 hours and allowed to cool down at ambient conditions. A uniform layer of iron oxyhydroxide (β-FeOOH) film (yellow in color) was formed on the FTO substrate. The β-FeOOH film was washed with distilled water to remove any residual salts. To convert β-FeOOH into hematite, the film was further sintered in air at 550 °C for 30 min, followed by annealing at 800 °C for additional 20 min.

Hematite nanoparticle film was prepared according to a previous study. 10 mM FeCl₃ ethanol solution was drop-deposited onto pre-cleaned FTO and blow-dried with compress air. The dried glass was heated on a hotplate in air at 350 °C for 5 min. This procedure was repeated for 20 times and the prepared films were then annealed in air at 550 °C for 4 h.

Ultrasonic treatment

A piece of α-Fe₂O₃/FTO was immersed in a beaker containing 20 ml of distilled water, and sonicated in a commercial sonicator (90W, 50 Hz) at room temperature for 10 s. For samples ultrasonically treated in saturated H₂O₂ and FeCl₃ (0.15 M) solution, the sonication times were 10 s and 10 min, respectively.
Material characterizations

To understand the effect of ultrasonication treatment, all the material characterizations were performed on the same sample(s) before and after sonication. The morphologies of hematite films were characterized by field emission scanning electron microscope (FE-SEM, Hitachi S-4800, 5kV). XRD patterns were characterized with a Rigaku Americas Miniflex Plus operating at 40 kV and 40 mA. XPS analysis was carried out on a Physical Electronics PHI 1600 ESCA system with an Al Kα X-ray source (E = 1486.6 eV). The binding energy was calibrated using the C 1s photoelectron peak at 284.6 eV as the reference. Laser Raman spectra (LRS) was performed on a Jobin-Yvon (France-Japan) T64000 type Laser Raman spectroscopy using Ar⁺ laser beam. Transmission electron microscopy (TEM) images were collected using a JEOL JEM-2100F TEM operated at 200 kV. UV-vis spectra of the samples were measured by a UV-vis-NIR Spectrophotometer (Shimadzu UV-2450). Attenuated total reflection Fourier transform infrared (ATR FTIR) spectra were collected on a Nicolet Nexus 5700. Contact angle measurements were carried out on a commercial instrument (OCA 20, DataPhysics Instruments GmbH, Filderstadt).

Photoelectrochemical and electrochemical measurements

Photoelectrochemical and electrochemical measurements of the electrodes were performed in a three-electrode configuration using hematite nanowire films as working electrode, saturated Ag/AgCl as reference electrode, and a platinum foil as counter electrode. 1.0 M KOH aqueous solution (pH 13.6) or 1.0 M KOH with 0.5 M H₂O₂ was used as the electrolyte. An electrochemical workstation (CHI 660D) was used to measure the current-voltage curves, current-time curves, and Mott-Schottky plots. Current-voltage curves of samples were measured at a scan rate of 10 mV/s under the irradiation of a 150 W xenon
lamp (100 mW/cm², Newport 6255) equipped with an AM 1.5G filter (Newport 81094). The illuminated area of the working electrode was 0.5 cm².

Electrochemical Impedance Spectroscopy (EIS) analysis was performed in a 1.0 M KOH aqueous solution over a frequency range from $10^5$ to 0.1 Hz. Data were fitted using Zsimpwin software. Mott-Schottky plots were obtained from the capacitance values at various potentials fitted from the dark EIS measurements.

**Supplementary Figures**

![SEM and TEM images of hematite nanowire films collected (a, c) before and (b, d) after sonication.](image)
