Summary: 16 Pages; 11 Figures and 2 Schemes
**Experimental details**

**Catalyst preparation**

The BiFeO$_3$ was synthesized in an aerosol-spraying reactor (Fig. S1). In a typical run of synthesis, 1.1 g Bi(NO$_3$)$_3$·5H$_2$O was dissolved in 48 mL ethanol containing desired glycerol. Then, 0.81 g Fe(NO$_3$)$_3$·9H$_2$O was added and stirred until the clear solution was obtained. Subsequently, the solution was atomized into aerosol droplets and then passed through a quartz glass tube at 800 °C with N$_2$ carrier gas (4.0 L/min). The solid particles collected on a filter were then calcined for 4 h at desired temperature to remove organic residues and promote crystal growth. The as-prepared samples were denoted as BFO-X-Y, where X and Y represent the glycerol amount (mL) in the initial aerogel solution and calcination temperature (°C), respectively. The samples before calcination were denoted as BFO-X. BFO-X-Y(G) represents the BiFeO$_3$ particles obtained by crushing the BFO-X-Y hollow spheres. For comparison, the BiFeO$_3$ in solid particles, denoted as BFO-SSR, was also prepared by solid-state reaction at 800 °C for 5 h following the procedures reported previously.$^7$

**Characterizations**

The structure was examined by Fourier transform infrared spectrometer (FTIR, NEXUS 470, samples pelletized with KBr, 32 scanning times) and X-ray diffraction (XRD, Rigacu D/Max-2000, monochromatic CuKa radiation, graphite curve monochromator, 0.02°(2θ) Scan step, 4°/min scan rate, 40 kV voltage, 30 mA current). Crystallite sizes were determined based on the Scherrer equation ($D = K\lambda/\beta\cos\theta$). Surface morphology was observed by transmission electronic microscopy (TEM, JEM-2010). X-ray photoelectron spectroscopy (XPS, Versa Probe PHI 5000, Al Kα excitation source, 10$^{-9}$ torr pressure in analysis chamber, 14.0 kV voltage) was employed to determine surface electronic states. The shift of the binding energy due to relative surface charging was corrected using the C$_{1s}$ level at 284.8 eV as an
Internal standard. Samples were pelletized into 5×5 mm sheet before measurement. N₂ adsorption-desorption isotherms were measured on a Quantachrome NOVA 4000e at 77 K. The Brunauer-Emmett-Teller (BET) method was used to calculate the specific surface area ($S_{BET}$) and the Barrett-Joyner-Halenda (BJH) model was used to calculate pore volume ($V_P$) and pore diameter ($D_P$). The thermal stability was investigated by a thermogravimetric analyzer (DTG-60H, 10 °C/min heating rate, 50 mL/min flow rate, referenced Al₂O₃ sample). The light absorption ability was analyzed by UV-vis diffuse reflectance spectra (DRS, MC-2530).

**Activity test**

The rhodamine B (RhB) photodegradation was carried out at 303 K in a self-designed quartz reactor containing 50 mL of 1.0 × 10⁻⁵ M RhB and 0.10 g catalyst. The mixture was stirred vigorously at the speed of 800 rpm to eliminate diffusion effect on the reaction kinetics. After reaching adsorption equilibrium, the photocatalytic reaction was initiated by irradiating with one 500 W Xe lamp (CHF-XM500, light intensity = 600 mW/cm²) located at 18 cm above the solution surface. To make sure that the photocatalytic reaction was really driven by visible lights, the lights with wavelength less than 420 nm were cut off by a glass filter (JB-420). Each run of reactions was lasted for 6 h and the unreacted RhB was analyzed by a UV spectrophotometer (UV 7504/PC) at their characteristic wavelength of 553 nm to determine the degradation yield. Preliminary experiments demonstrated that only less than 8% RhB was decomposed after reaction for 6 h in the absence of either the photocatalyst or light irradiation, and thus could be neglected in comparison with degradation yield resulting from photocatalysis. The reproducibility of the results was checked by repeating each reaction at least three times and was found to be within acceptable limits (± 5%).
