In-situ X-ray absorption spectroscopy. In situ X-ray absorption spectroscopic data were collected on a Pt/C (30\%, E-TEK) sample as a function of electrode potentials (+0.01 V, +0.24 V, +0.54 V, +0.84 V, and +1.04 V) in 0.1 M HClO\textsubscript{4} and 0.1 M HClO\textsubscript{4} + 100 mM phosphoric acid. All data were processed with standard procedures using the IFEFFIT suite (v.1.2.9) \cite{1}. Briefly, the reference foils corresponding to each scan were calibrated to the standard Pt L\textsubscript{3} edge energy and then carefully aligned to a selected standard at +0.54 V. The energy shifts were then automatically applied to all the respective sample scans. Difference spectra were obtained to isolate the effect of adsorbate by using the following equation,

\[
\Delta \mu(x,y) = \mu(y \text{ V}, 0.1 \text{ M HClO}_4 + x \text{ M H}_3\text{PO}_4) - \mu(+0.54 \text{ V}, 0.1 \text{ M HClO}_4)
\]  

where \( \mu \) is the X-ray absorption coefficient at the electrode potential of \( y \text{ V} \) and at \( \text{H}_3\text{PO}_4 \) concentration of \( x \text{ M} \). In a series of previous studies using the XANES-based \( \Delta \mu \) technique \cite{2-4}, Pt catalyst surfaces were found to be the 'cleanest' and relatively free of any adsorbates at around
+0.5 V in acid media; therefore the data at +0.54 V in 0.1 M HClO₄ were used as the reference to generate the difference spectra in the present study.

Figure S1 shows the ∆µ curves for the Pt/C (E-TEK) catalyst samples in (a) 0.1 M HClO₄ and (b) 0.1 M HClO₄ + 100 mM H₃PO₄. The signatures correspond very well to H/Pt adsorbed in 3-fold sites [3], and the magnitude of the H/Pt signature decreased with increasing electrode potential. Note that the absorption spectrum at +0.54 V in 0.1 M HClO₄ was used as the reference spectrum in the calculation of ∆µ. In 0.1 M HClO₄ + 100 mM H₃PO₄, the ∆µ curve at +0.54 V exhibits a small negative feature at ca. 0 eV followed by a small, broad positive feature of roughly the same magnitude at ca. 5 eV. Considering that oxygen did not bond to the Pt surface at such low potentials and that the magnitude of the positive feature was much smaller than for a strongly bonded 3-fold O/Pt, it is likely that this is due to the more weakly bonded $H_2PO_4^-$/Pt with the

Figure S2. Theoretical simulations of ∆µ signatures of $H_2PO_4^-$ adsorption on Pt by FEFF 8.0
oxygen occupying the 3-fold hollow sites on the Pt surface. This is very similar to the line shape found previously for 3-fold Cl/Pt [5]. As the potential was increased to +0.84 V and +1.04 V, the line shape approaches the theoretical 3-fold mode depicted in Figure S2, along with a negative peak close to 0 eV.

**Additional Electrochemical Data**
