The AQS/PANI hybrid film was synthesized by an electrochemical doping–dedoping–redoping method. Before electropolymerization, the graphite disk electrode impregnated with paraffin was polished to a mirror-like surface with fine alumina powder and cleaned by mild sonication in pure water. Then, the working electrode was cycled in potential range from –0.5 V to 1.8 V at 50 mV s\(^{-1}\) in N\(_2\)-saturated 0.1 mol L\(^{-1}\) H\(_2\)SO\(_4\) solution in order to activate the electrode. In the doping process, freshly distilled aniline was \textit{in situ} electropolymerized on working electrode by CV method in 0.1 mol L\(^{-1}\) H\(_2\)SO\(_4\) solution containing 0.1 mol L\(^{-1}\) aniline, resulting in the emeraldine salt form of PANI (ES-PANI). Then, the SO\(_4^{2-}\) anion was removed from the resulting film to obtain the emeraldine base form of PANI (EB-PANI) by dedoping method. After dedoping, the obtained EB-PANI was redoped with AQS to prepare the AQS/PANI hybrid film. A typical example for the preparation of AQS/PANI hybrid film by the electrochemical doping-dedoping-redoping method is given as follows:

The deposition of ES-PANI films on working electrode was performed by CV method rather than using a constant current method, since it was found that films deposited by cycling display lower background currents, and thus better insulating properties at the negative end of voltage span. Thin PANI film was grown on graphite disk electrode in 0.1 mol L\(^{-1}\) H\(_2\)SO\(_4\) + 0.1 mol L\(^{-1}\) aniline solution under N\(_2\) atmosphere to obtain ES-PANI, using the following methodology: (a) first and second cycles—potentiodynamic polymerization by cycling at 2 mV s\(^{-1}\) from –0.2 V to +0.9 V; (b) other cycles (up to 20)—potential cycling between –0.2 V and +0.7 V at 10 mV s\(^{-1}\) at room temperature. Then, the ES-PANI was dedoped firstly by potentiostatic treatment at –0.2 V in aniline monomer free N\(_2\)-saturated 0.1 mol L\(^{-1}\) H\(_2\)SO\(_4\) solution for 40 min, followed by immersing it in 0.1 mol L\(^{-1}\) NH\(_4\)OH at room temperature for 2 h and then in ice cold distilled water for 2 h to remove doped or physically adsorbed SO\(_4^{2-}\) anion, and thus obtain the EB-PANI.

After dedoping by potentiostatic treatment and immersed in NH\(_4\)OH aqueous solution and ice water, the EB-PANI was redoped also by CV method at 10 mV s\(^{-1}\) from –0.2 V to +0.75 V in N\(_2\)-saturated 0.1 mol L\(^{-1}\) H\(_2\)SO\(_4\) solution containing 5 mmol L\(^{-1}\) AQS. This redoping process is assumed to be counter-
ion doping during PANI oxidation, and is an irreversible process due to the big bulk of doping AQS ($AQS_{\text{doping}}$). The electrode was cycled repeatedly until stable cyclic voltammograms were obtained and thus get the AQS/PANI hybrid film. The preparation details can be illustrated in Scheme S1. The resulting electrode was washed with distilled water and ethanol and then dried in a vacuum overnight at 60 °C before use.

**Thermogravimetric analysis/Simultaneous differential thermal analysis (TGA/SDTA)**

Thermal degradation studies were performed under nitrogen atmosphere at a linear heating rate of 10 °C/min from room temperature to 500 °C. TGA/SDTA measurement of the AQS/PANI hybrid film shown in Fig. S1 indicates that the mass loss undergoes three steps: (1) starts at 50 °C and continues up
to 100 °C; (2) a slow weight loss in the temperature range from 100 to 300 °C; and (3) a significant mass loss up to 500 °C. For the first-step weight loss, the AQS/PANI hybrid film shows 2–5% weight loss, which is attributed to the loss of surface water.\textsuperscript{1-3} SDTA measurement suggests that this step is endothermic process. We interpreted the second-step weight loss as dopant loss (AQS\textsubscript{doping} dedoping). The third-step weight loss starting at 300 °C and up to 500 °C is due to the decomposition of AQS/PANI hybrid film, which corresponds to the decomposition temperature, 296 – 300 °C, of AQS\textsubscript{doping}. This result is consistent well with the fact that ES forms of PANI films begin to decompose at a temperature much lower than the decompose temperature of EB (around 500 °C).\textsuperscript{1} In addition, it is an exothermic process according to the SDTA curve.

The stability of AQS/PANI hybrid film

The performance of the AQS/PANI hybrid film modified electrode towards ORR in pH 3.07 O\textsubscript{2}-saturated solution was further investigated by single potential-step chronoamperometry method at a cathodic potential of −0.5 V for over 3–4 hours at room temperature. During test, O\textsubscript{2} gas was continuously bubbled around the working electrode. As seen from Fig. S2, the AQS/PANI hybrid film modified electrode is quite stable as it produces an approximately constant value of oxygen reduction current during the entire period of investigation. This result should be firstly attributed to the excellent environmental stability of PANI layer. On the other hand, AQS on account of its high degree of...
planarity contributes also to the stability of hybrid film, because the stability and the electronic conductivity of conducting polymer films doped with various anthraquinone sulfonate correlate well with the number of sulfonate groups attached, and the best result attained at one sulfonate group per dopant molecule.\(^4\)
