**Figure S1** Hue values for different colours (top) and that of a mixture of two 10 µl drops containing varying concentrations of blue and yellow dye (bottom). The data was linearly fitted with $R^2 = 0.989$ ($n = 5$).

**Figure S2** Mixing intensity (the normalised hue value given in Eq. (1) averaged across the pixels in a cross-section of the channel at several predetermined locations) as a function of time for the curved channel shown in Fig. 1(b). The normalised value of the fully unmixed (blue or yellow) states is 1 and approximately 0 for the fully mixed (green) state. We note that there is a slight increase in the hue value at the beginning of the experiment due to the initial filling of the channel; the steady hue values in the reservoirs, on the other hand, are accounted for in the normalisation of Eq. (1).

Figure S3 Comparison of the transverse concentration profile predicted by the standard convective-diffusive model (solid line) with that observed in the experiment (points) at a representative midpoint location along the channel $x^* = 10$. At a power of 2 W, the experimentally determined SAW-driven flow velocity $U$ is $1.33 \times 10^{-3}$ m/s in the 2 mm wide channel, corresponding to $Pe = 2600$. We note that the analytical prediction significantly underpredicts the mixing. To roughly quantify the mixing enhancement, we match the experimental concentration profile to the analytical solution with a modified Péclét number $Pe_{\text{eff}}$, which essentially corresponds to an effective diffusion coefficient $D_{\text{eff}}$. It can be seen that the experimental and analytical (bold solid line) profiles roughly match with a tenfold increase in the diffusivity, i.e., $D_{\text{eff}} = 10D_o$, and hence an order of magnitude decrease in $Pe$, i.e., $Pe_{\text{eff}} = 260$. Also shown by the dotted and dashed lines is the effect of increasing the input power of the SAW (associated with a corresponding increase in the flow velocity $U$), captured through an effective Péclét number in the analytical solution. In any case, the similar shaped trends between the experimental and analytical concentration profiles suggest that the mixing in the paper takes place through diffusion between the two laminar streams although we note that the interface between the streams is located at a slight offset from the middle of the channel $y^* = 0.5$ due to slight irregularities along the paper surface.
