Table S1. Pore parameters of the NC@MoS₂ core-shell microspheres with different MoS₂ contents.

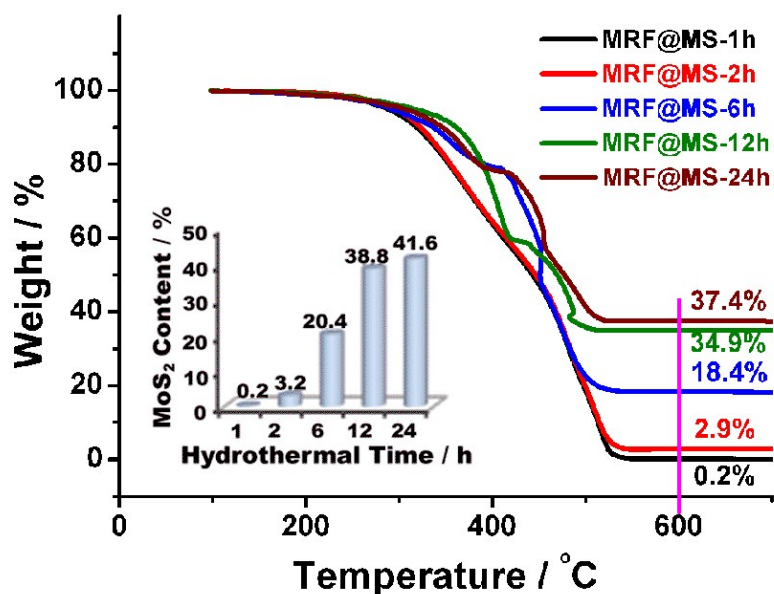

Figure S1. TG analysis in air of as-synthesized MRF@MoS₂ microspheres at different hydrothermal times without heat-treatment (denoted as MRF@MoS₂-xh, where x represents the hydrothermal time). The MRF@MoS₂ microspheres underwent significant weight loss mainly below 550 °C, which can perhaps be attributed to combustion of MRF polymer microspheres, and oxidation of MoS₂ to MoO₃. By assuming that the remaining product after the TGA measurement is MoO₃, the MoS₂ contents in the MRF@MoS₂ microspheres could be calculated, as shown in the inset. After the initial hydrothermal time of 1 h, the collected samples are MRF polymer microspheres and contain almost no MoS₂. After hydrothermal reaction for 2 h, the MRF microsphere surfaces are covered by MoS₂ nuclei nanoparticles with a content of 3.2 wt.%. The MoS₂ contents increase from 20.4 wt.% for MRF@MS-6h composites to 38.8 wt.% for MRF@MS-12h composites and 41.6 wt.% for MRF@MS-24h composites, further confirming the continuous growth of MoS₂ nanowalls during the hydrothermal process.

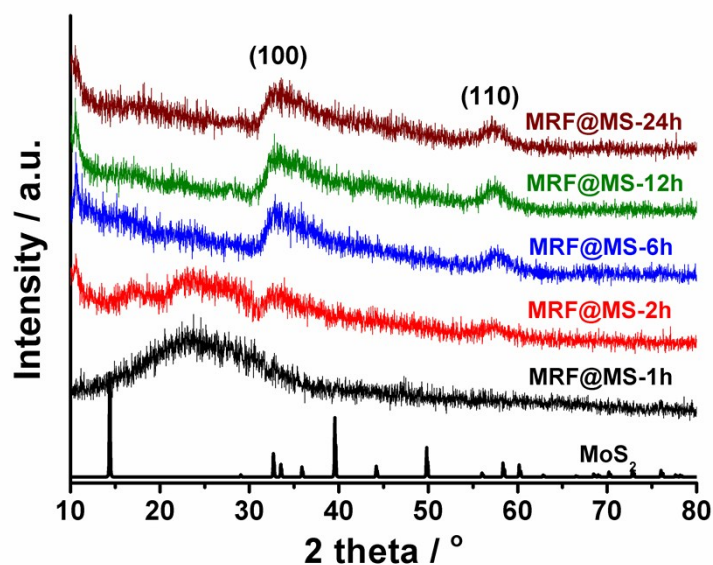

Figure S2. XRD patterns of as-synthesized MRF@MoS₂ microspheres at different hydrothermal times without heat-treatment (denoted as MRF@MoS₂-xh, where x represents the hydrothermal time). No MoS₂ diffraction peaks are present and a wide diffraction peak (2θ) is obviously observed at around 24.2° that corresponds to the pure MRF polymer in the collected samples after hydrothermal reaction for 1 h. After hydrothermal time for 2-24 h, two weak peaks at 32.8° and 57.5° can be found which are respectively attributed to the (100) and (110) crystal planes of typical hexagonal 2H-MoS₂. These results further suggest the direct coverage of MoS₂ on the fast formed MRF polymer microspheres.

Figure S3. (a) and (b) SEM images of as-synthesized RF/MoS₂ composites without the addition of melamine in the initial hydrothermal precursors. The RF/MoS₂ composites show irregular morphology with a small amount of MoS₂ nanowalls decorated on the RF polymer particles. It is evident that the melamine could be key on the formation of the core-shell microspherical morphology.

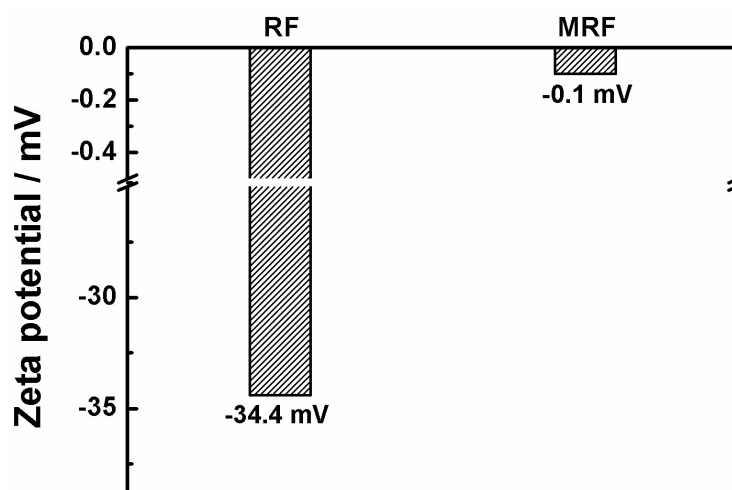

Figure S4. Zeta potential of the RF and MRF colloidal microspheres. The pure RF and MRF polymeric microspheres were prepared through the hydrothermal method without the addition of Na_2MoO_4 and NH_2CSNH_2 as reported in our previous work (H. Zhou, S. Xu, H. Su, et al. *Chem. Commun.*, 2013, **49**, 3763). The RF colloidal microspheres are highly negatively charged with a Zeta potential value of -34.4 mV. The nitrogen functionality inherited from melamine precursor could apparently increase the surface charge of the MRF colloidal microspheres. This increased surface charge of MRF microsphere caused by nitrogen functionality is favorable for the adsorption of MoO_4^{2-} anion and subsequent coating of MoS_2 due to the reduced electrostatic repulsion force, which could further inhibit the continuous growth of MRF microspheres.

Figure S5. (a) The SEM image of the cracked NC@70MS core-shell microspheres; (b) Elemental EDX analysis of the core region (the red rectangle indication) and the shell region (the green rectangle indication) in (a). The SEM image of the cracked microspheres confirms the cores are in the middle site of the microspheres due to the conformal coverage of the shells. EDX characterizations give the stronger signals of Mo/S in the shell region and the stronger signal of C in the core region respectively. These significant differences further confirm that the NC@MoS₂ microspheres are composed of the carbon cores and the MoS₂ shells. However, due to the semi-quantitative features of the EDX method, the MoS₂ content in the microspheres obtained from EDX analysis is very different from that determined by TGA analysis. Furthermore, it is calculated that the atomic ratio of Mo to S approaches the theoretical value of 1/2, further suggesting the formation of stoichiometric MoS₂.

Figure S6. Raman spectra of the NC@70MS core-shell microspheres. The Raman spectra of the NC@70MS core-shell microspheres shows the typical characteristic E_{2g} and A_{1g} bands of MoS₂, located at ca. 380.7 and 406.5 cm⁻¹, respectively. The E_{2g} mode involves the in-layer displacements of Mo and S atoms whereas the A_{1g} mode involves the out-of-layer symmetric displacements of S atoms along the c -axis. The Raman peaks at 1356 cm⁻¹ and 1593 cm⁻¹ are respectively assigned to the typical characteristic D- and G- bands of disordered graphitic carbon materials.

Figure S7. (a) SEM image of the NC@50MS core-shell microspheres and (b) HRTEM image of the MoS₂ nanowalls. The NC@50MS core-shell microspheres have the hierarchical MoS₂ shells constituted of few-layered MoS₂ nanowalls with a similar interlayer spacing as other three samples.

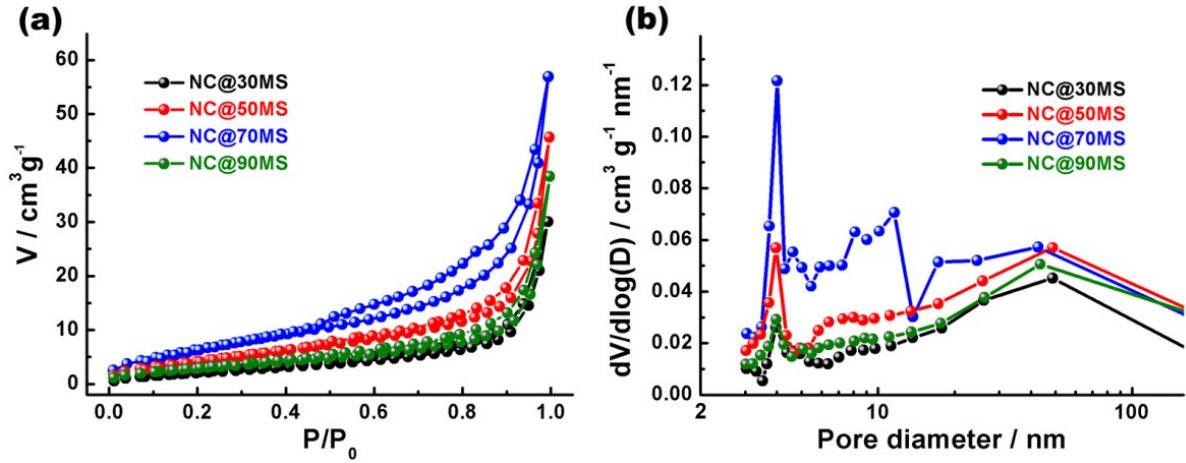

Figure S8. (a) N₂ adsorption-desorption isotherms and (b) BJH pore size distributions of the NC@MoS₂ core-shell microspheres with different MoS₂ contents. All isothermals exhibit the type-IV behaviours with pronounced adsorptions at high relative pressures (0.8-1.0 P/P_0), suggesting that mesopores and macropores coexist in the NC@MoS₂ core-shell microspheres. The mesoporous and macroporous structures are a result of the inter-connection of the ultrathin MoS₂ nanowalls. The NC@70MS core-shell microspheres have a BET surface area of 26 m² g⁻¹ and a total pore volume of 0.1 cm³ g⁻¹. The detail pore parameters of the NC@MoS₂ core-shell microspheres with different MoS₂ contents were listed in Table S1. Such hierarchical porous structures could not only facilitate the diffusion of Li-ion, but also accommodate the large volume expansion during the charge-discharge cycles.

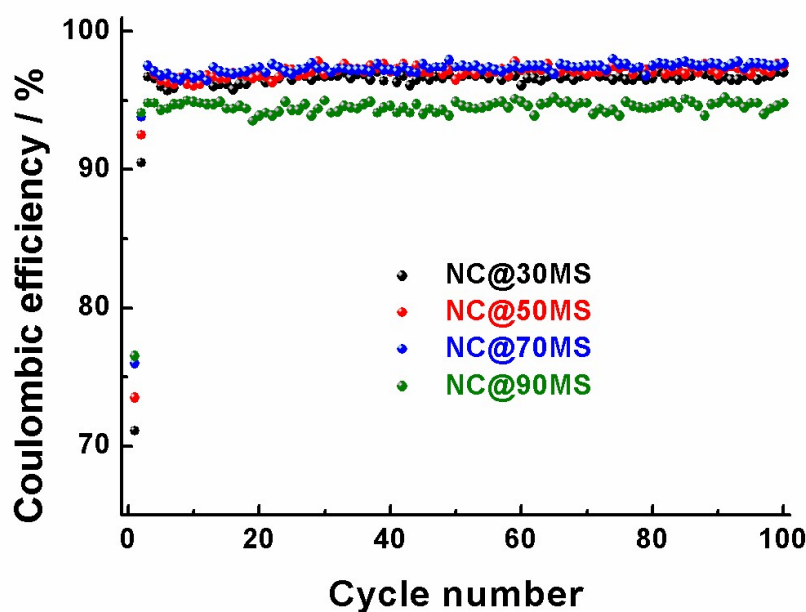

Figure S9. Coulombic efficiency of the NC@MoS₂ core-shell microspheres with different MoS₂ contents. The initial coulombic efficiency of the NC@70MS core-shell microspheres is 76%. The initial irreversible capacity loss could be mainly attributed to the formation of the thick gel-like polymeric layer from the electrochemically driven electrolyte degradation, or the trapping of lithium inside the lattice. The coulombic efficiency of the NC@70MS core-shell microspheres increases to 93.8% for the second cycle, 97.5% for the third cycle and 97.7% after 100 cycles, suggesting the excellent structure stability upon cycles. The NC@90MS core-shell microspheres exhibit a lower coulombic efficiency of 94.8% after 100 cycles, possibly due to the significant deterioration of electronic/ionic conductivity caused by the excess MoS₂ coverage.

Figure S10. Cycle performance of the nitrogen-doped carbon microspheres (NC) carbonized from the MRF polymer microspheres at a current rate of 100 mA g^{-1} . The specific capacity of NC is 298.9 mAh g^{-1} after 100 cycles, significantly lower than that of MoS_2 .

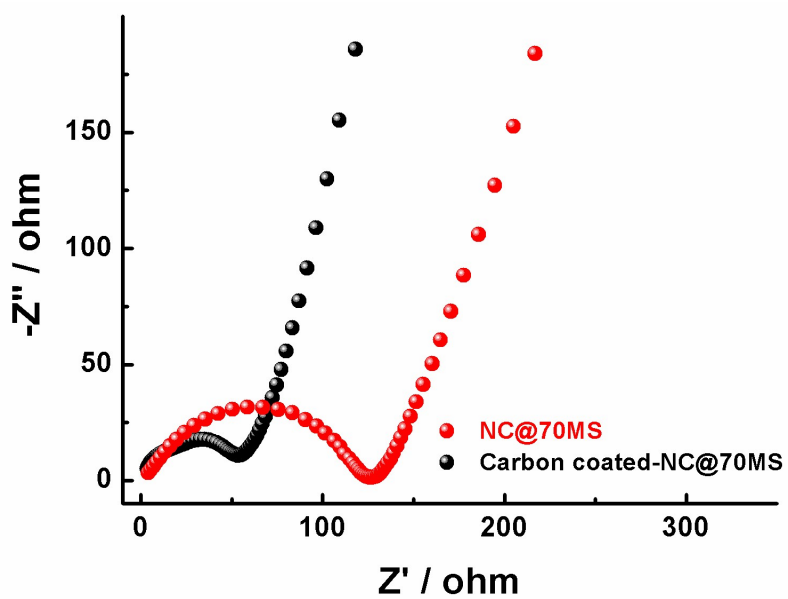

Figure S11. EIS before the first cycle of the NC@70MS core-shell microspheres and the carbon coated-NC@70MS microspheres. The carbon coated-NC@70MS microspheres exhibit faster charge-transfer kinetics than the NC@70MS core-shell microspheres.

Table S1. Pore parameters of the NC@MoS₂ core-shell microspheres with different MoS₂ contents.

Sample	S _{BET} / m ² g ⁻¹	V _t / cm ³ g ⁻¹
NC@30MS	9	0.05
NC@50MS	17	0.07
NC@70MS	26	0.09
NC@90MS	12	0.06
