

SUPPLEMENTARY INFORMATION

ANALYSIS OF RAMAN SPECTRA

Figure 2 in the main text includes the Raman spectra, which provides information about the structural organization of the free carbon phase in PDCs. The representative features of free carbon in Raman spectra are the so called disorder induced D band at approximately 1350 cm^{-1} and the G band at approximately 1580 cm^{-1} due to in-plane bond stretching of sp^2 carbon.

Figure 2a shows that up to 1023 K the Raman spectra of the TTCS derived powders exhibit no significant feature due to a completely amorphous carbon phase,⁷⁹ while in the Raman spectrum obtained after pyrolysing up to 1273 K both the D and G bands appear due to the formation of free carbon nanocrystalline clusters and G'-band,⁷⁴⁻⁷⁸. Figure 2b includes the Raman spectra of the residues obtained of the pyrolysed CERASET precursor. In these residues, no significant features are noticed even at 1273 K, with only a very broad band due to a completely amorphous carbon phase. The lack of features of the Raman spectra obtained of the Ceraset derived SiCN ceramic might be striking at first since that composition usually exhibits well defined D and G bands at that temperature. However, it should be noted that samples reported in literature are mostly prepared by heating the crosslinked precursor in a furnace up to 900-1000°C for at least 1 or 2 hours in order to complete the ceramification process. In our case, we have measured the Raman spectra on powder samples retrieved directly from the TGA instrument after heating at a given temperature (550, 750 and 1000°C) and then quenched to stop the reaction. This shows that just reaching 1000 °C is not enough to fully develop the nanocrystalline structure of the free carbon in the ceramic but keeping the temperature for a minimum time might be necessary.

We have used the same Ceraset precursor to fabricate cylindrical pellets using more conventional procedures (heating up to 1000 to 1400 °C and keeping the temperatures for 2 hours in a conventional furnace). In those cases we obtained the usual Raman spectra observed in these compositions, as shown in the figure below:

However, SiCO ceramics display reasonably well-defined D and G peaks after the same experimental procedure. This different behavior might be explained in terms of free carbon content, which is slightly under 20% in SiCN and about 35% in SiCO. It would be reasonable to assume that the formation of the nanocrystalline carbon domains large enough to be observed by Raman would be favoured in a composition with a higher carbon content.

ANALYSIS OF FTIR SPECTRA

Figure 3a in the main text shows the FTIR spectra of the cross-linked TTCS polymer and the subsequent powders obtained at 823 K, 1023 K and 1273 K. The figure shows the gradual transformation of the initial polymeric network into the final SiCO ceramic. Initially, the polymer network features bands at $\sim 800\text{-}900\text{ cm}^{-1}$ are observed due to vibrations of Si-H bonds,⁸⁰ as well as bands at 2880 cm^{-1} and 1140 cm^{-1} , which are related to ethylene groups⁸⁰. Such bands decrease in intensity with the temperature as the organic groups are cleaved and released, and are completely absent in the powder obtained at 1023 K. The bands at 2960 , 1406 and 1260 cm^{-1} are produced by CH_3 groups⁸⁰ and also decrease with the pyrolysis temperature. The rearrangements of the bands at 1030 cm^{-1} due to Si-O bond asymmetric stretching vibrations⁸⁰ can be observed. The spectrum of the final SiCO ceramic shows only broad bands at 1031 , 823 and 452 cm^{-1} corresponding to of Si-O and Si-C bonds vibrations. Figure 3b includes the FTIR spectra of the cross-linked CERASET polymer and the powders pyrolysed at 823 K, 1023 K and 1273 K. The spectra recorded for the powders collected at 823K presents features bands that can be attributed to N-H (3383 cm^{-1}), Si-H (2129 cm^{-1}), Si-N (794 and 898 cm^{-1}), C-H (2900 , 2957 and 3048 cm^{-1}), $\text{CH}=\text{CH}_2$ (1593 cm^{-1}) and Si- CH_3 (1255 cm^{-1}). At 1023 K most of the aforementioned bands are absent and only appear broad bands at $750\text{-}1200\text{ cm}^{-1}$, 2129 cm^{-1} and $3000\text{-}3400\text{ cm}^{-1}$, attributed to Si-N, Si-H and N-H respectively⁸¹. At 1273 K only the broad Si-N band is noticeable.

KINETIC ANALYSIS – DECONVOLUTION OF EXPERIMENTAL COMPLEX CURVES

Table S1. Fitting parameters (a_0 , a_1 , a_2 y a_3) obtained by Fraser-Suzuki deconvolution of the experimental kinetic curve obtained for the thermal decomposition of TTCS precursor curves using Peakfit software.

THERMAL DECOMPOSITION TTCS PRECURSOR
