Section 2. Absorption and Emission Spectroscopy

Emission color calculation

From the experimental emission spectra, the perceived colors by the human eye may be estimated following a very simple procedure using the standard CIE (2°) 1931 color space, which allows calculating the xy chromaticity coordinates [1]. The overlap between the emission spectra, $\varepsilon(\lambda)$, and the color matching function, $\bar{x}(\lambda)$ in the visible range yields the X tristimulus value (equation 1). For the numerical integration, a 1 nm increment is sufficient to attain accurate results. The Y and Z tristimulus values may be calculated analogously with the corresponding $\bar{y}(\lambda)$ and $\bar{z}(\lambda)$ color matching functions (CMFs). These CMFs describe the observer in a given color space, characterizing its chromatic response. Their values may be found tabulated in the literature [2].

$$X = \int_{\text{visible}} \bar{x}(\lambda) \varepsilon(\lambda) d\lambda \quad (1)$$

Finally, the x and y chromaticity coordinates are calculated as:

$$x = \frac{X}{X + Y + Z} \quad y = \frac{Y}{X + Y + Z} \quad (2)$$

Section 3. Theory and Computation

Molecular geometries

In both structures, the crystal monomer and the optimized singlet ground state, the angles between trans ligands are very similar and in the range of 170-180°. The largest differences arise in the Ir-C, Ir-N and Ir-Cl bond lengths, which are overestimated by ~0.05-0.09 Å in the optimized geometries. Intermolecular effects in the crystal could be responsible for the difference in the Ir-Cl bond length but don't seem to be responsible for the differences in the Ir-C and Ir-N bond lengths, thus, we attribute these to the inherent approximations of the computational methodology. Superposition of both structures reveals that the phosphine ligands are practically identical in both geometries. Comparison of the two phosphine ligands in the complex reveals that they are enantiomers, with the iridium's equatorial plane acting as the mirror plane (Figure S20).

Figure S28. Different views of the superposition of the crystal's monomer (green) of complex **2** with the optimized ground state (blue) and lowest triplet state (red) at the B3LYP/LANL2DZ,6-31G(d) level. Hydrogen atoms have been omitted for the sake of clarity.

Table S2. Selected geometrical parameters of the iridium's coordination environment and the imine group (C-N, N=C and C-C) in the crystal (x-ray structure) and for the S_0 and T_1 states of complex **2** optimized at the B3LYP/LANL2DZ,6-31G(d) level.

	bond lengths (Å)								angles (°)		
	Ir-C	Ir-Cl	Ir-N	Ir-H	Ir-P	C-N	N=C	C-C	C-Ir-Cl	N-Ir-H	P-Ir-P

Molecular orbitals

From the HOMO to HOMO-7 (Figure S29), there are only two orbitals that do not have participation of the iridium atom. That is, HOMO-3 which is a combination of the non-bonding orbital of the nitrogen atom of the imine unit with the p_x orbital of the chloride ligand, and HOMO-5 which is a π -orbital of the phenyl ring of the Schiff base ligand. LUMO+1 is mainly a d_{z^2} type orbital with some participation of π -type orbitals of the phenyl rings of the phosphines and lies ~ 0.6 eV above the LUMO due to the anti-bonding interaction with the lone pair of the phosphorous. The $d_{x^2-y^2}$ type orbital on the other hand, appears rather high in energy due to strong anti-bonding interactions with orbitals of the hydride ligand, the phosphorus atoms and the nitrogen of the Schiff base.

Emission spectra of 1-3

Our calculations predict the $^3\text{MLLCTz/LC}$ state as the one responsible for the phosphorescence emission of complexes **1-3**. For all three complexes there is a nice agreement between experimental emission spectra and the simulated vibrationally resolved phosphorescence profiles (Figures 6, S32 and S33). Each spectrum has clearly three peaks at the short wavelength region and several less intense shoulders at long wavelengths. The relative positions of the well-resolved peaks in the emission band are correctly reproduced by our calculations, but the relative intensities are, in some cases, not correctly estimated, especially for the peak just above 500 nm. Although the peak at ~ 550 nm is also the most intense in our calculations, the relative intensities with the two neighboring peaks are over and underestimated, respectively. The blue shift of the 0-0 transition with respect to the convoluted peak at ~ 500 nm is due to the presence of nearby transitions which contribute to the band's intensity.

For complexes **1-3**, the main vibrational mode responsible for the structured emission is related to the stretching of the C=N bond in the Schiff base, with a computed frequency of $\sim 1470\text{-}1450\text{ cm}^{-1}$ (Figure S34). The distortion associated with this mode is in fact the main geometrical modification along the molecular relaxation on the T_1 state potential energy surface from the Franck-Condon region. Although this vibrational progression is the one that apparently causes the overall shape of the emission spectra, there are also other normal modes contributing to the emission profiles (Tables S5-S8). Apart from the C=N vibronic progression, there are combinations of modes of the imine unit with modes involving the phenyl rings of the PPh_3 ligands. Since the modifications in the ancillary ligand of complexes **1-3** do not have a great impact on the C=N stretching mode, the peaks of the vibrational progressions in the emission spectra are similarly spaced out in the three complexes and the relative intensities are alike. The main effect of the substitution is therefore in tuning the energy of the electronic transition from the T_1 state back to the ground state, and not in the modification of the overall shape of the emission spectrum.

Figure S32. Simulated (solid) and experimental (dashed) emission spectra of complex **1** together with the calculated stick spectrum obtained at the B3LYP/LANL2DZ,6-31G(d) computational level. Both spectra have been normalized and the calculated spectrum has been blue shifted by 0.09 eV to superimpose the most intense peaks. The 202 normal mode of vibration corresponds to the C=N stretching mode of the imine.

Figure S33. Simulated (solid) and experimental (dashed) emission spectra of complex **3** together with the calculated stick spectrum obtained at the B3LYP/LANL2DZ,6-31G(d) computational level. Both spectra have been normalized and the calculated spectrum has

been blue shifted by 0.12 eV to superimpose the most intense peaks. The 210 normal mode of vibration corresponds to the C=N stretching mode of the imine.

Figure S34. Displacement vectors of the normal mode responsible for the vibronic progressions observed in the emission spectra of complex **2**. The triphenylphosphine ligands have been omitted for greater clarity.

Torsion of the Schiff base ligand in complex **4**

To further explore the nature of the lowest spin singlet electronic transition in complex **4**, which corresponds to the intra-ligand charge transfer singlet state ($^1\text{ILCT}$) localized on the Schiff base ligand, we compute its energy profile in benzene and DMSO along the molecular torsion of the diphenylamine donor group in the Schiff base ligand (Figure S35).

Figure S35. Molecular torsion in the Schiff base ligand of complex **4**.

Our results (Figure S36) indicate that the potential energy minimum of $^1\text{ILCT}$ corresponds to the same dihedral angle between the phenyl rings of the donor group and the planar Schiff base ligand obtained for the optimized ground state. Moreover, this picture is virtually the same for the two explored solvents. These results force us to rule out the formation of a twisted intramolecular charge transfer (TICT) state.

Figure S36. Energy profiles of the ground (S_0) and $^1\text{ILCT}$ (S_1) states of complex **4** along the molecular torsion in benzene (left) and DMSO (right) computed at the CAM-B3LYP level.

Figure S37. Side view of the C-H...Cl interactions of **2** shown in Figure 11 between a complex in the reference chain (red) and complexes of the blue chains.

Figure S38. Optimized S_0 geometry of **2H**. Hydrogen atoms of the PPh_3 ligands are omitted for the sake of clarity.

Table S9. Relative energies (in kcal/mol) of different protonated forms of complexes **1** and **4** (Scheme S1).

complex	Protonated site	
	N2	N3
1	0.0	12.3
4	0.0	35.2

Scheme S1. Complexes **1** and **4** with labels of N atoms corresponding to Table S8 protonated sites.

Table S10. Selected geometrical parameters of the iridium's coordination environment and of the imine group (C-N, N=C and C-C) for the optimized S_0 and T_1 states of **2H**. In Δ , the difference of the optimized S_0 geometrical parameters of **2H** relative to the original optimized S_0 of **2** are shown. The δ dihedral angle corresponds to the $N=C_1-C_2-C_3$ shown in Figure S38.

geometry	bond lengths (Å)							
	Ir-C	Ir-Cl	Ir-N	Ir-H	Ir-P	C-N	N=C	C-C
S_0	1.965	2.491	2.213	1.585	2.443	1.397	1.362	1.474
T_1	2.064	2.401	2.188	1.588	2.459	1.357	1.394	1.439
Δ	-0.056	-0.070	0.037	-0.016	0.043	0.024	0.039	-0.020

geometry	angles (°)			
	C-Ir-Cl	N-Ir-H	P-Ir-P	δ
S_0	176	174	168	22
T_1	163	157	175	21
Δ	5	-1	-0	22

Figure S39. Representation of the molecular orbital diagram of complex **2** in its neutral (left) and protonated (right) forms. MLLCTz and MLLCTy labels indicate occupied MOs contributing to the corresponding lowest lying triplet states. Note: distribution of the MOs along the vertical axis only corresponds to a qualitative schematic representation of their relative energy.

Table S11. Excitation energies (in eV) to the two lowest lying triplet states of complex **2** and its protonated form (**2H**).

Complex 2		Complex 2H	
Character	Energy	Character	Energy
MLLCTz/LC	2.63	MLLCTz	2.69
MLLCTy	3.12	MLLCTy	2.61

Table S12. HOMO and LUMO energies (in eV) of complex **4** computed with CAM-B3LYP in benzene and DMSO solution. Δ indicates $E(\text{DMSO}) - E(\text{benzene})$.

Character	Benzene	DMSO	Δ
LUMO	-0.70	-0.92	-0.12
HOMO	-6.04	-6.19	-0.08
