Scheme S1. Overview of aromatic monomer production from xylenes and facile xylenes substitution by tolualdehydes

Tolualdehydes are partially oxidized xylenes. Because the first step in the production of phthalic anhydride and terephthalic acid involves the oxidation of xylenes to toluic acids,^{1,2} tolualdehydes are viable xylene replacements in the synthesis of these aromatic monomers.

Details of the co-precipitation synthesis:

To 50 mL of deionized (DI) water under a N₂ atmosphere, Mg(NO₃)₃· 6H₂O and Al(NO₃)₃· 9H₂O were added such that the desired molar Mg/Al ratios (2 and 3, corresponding to Al fractions of 0.33 and 0.25, respectively) and a total metal cation concentration $[Mg^{2+} + Al^{3+}] = 1.2 M$ were achieved. This solution was added dropwise under vigorous stirring to a round bottom flask containing 150 mL of DI water and Na₂CO₃. The amount of Na₂CO₃ added was determined from the amount of charge-compensating CO₃²⁻ anions necessary to balance the excess positive charge in the LDH layers due to the Al³⁺ incorporation ($[CO_3^{2-}] =$ 0.5 [Al³⁺]), taken with a 20% excess. The pH was maintained at 10 by co-feeding a 2 *M* solution of NaOH dropwise to the round bottom flask. After the addition was complete, the solution was statically aged in an oil bath at 75 °C for 18 hours. The formed precipitate was vacuum filtered and washed with copious amounts of DI water until the pH of the filtrate reached 7. The LDH was then dried overnight at 80 °C. Pure Mg(OH)₂ and Al(OH)₃ were synthesized using the same recipe with only Mg(NO₃)₃· 6H₂O and Al(NO₃)₃· 9H₂O, respectively.

Figure S1. XRD patterns for (a) the Mg-Al layered double hydroxides (Mg_xAl-LDH) and (b) Mg(OH)₂.

Figure S2. (a) Rietveld refinement of the XRD patterns with experimental (dark green and red) and calculated (lime for periclase, dark gray for spinel) curves and calculated phase (periclase, spinel-type) fractions. Goodness of fit values were between 2.2 and 2.3. (b) The lattice parameter *a*, calculated from the diffraction angle of the (200) plane in periclase, the Miller indices of this plane, and Bragg's Law, linearly decreases with increasing Al content due to the smaller radius of Al (0.535 Å) compared to Mg (0.720 Å). This indicates that Al isomorphically substitutes for Mg in the periclase phase.^{3,4}

Figure S3. ²⁷Al MAS NMR spectra for Mg_xAl-ox show two broad resonances attributed to octahedral and tetrahedral Al³⁺. Chemical shift values (in ppm) are labeled under each resonance. In the periclase phase,

Al_o arises from the isomorphic substitution of Mg²⁺ with Al³⁺, while Al_T comes from Al incorporation into the tetrahedral holes of the FCC lattice-during calcination of the Mg-Al LDH, some of the Alo in the brucite-like layers reduces to tetrahedral coordination to alleviate the bonding loss at the onset of layer dehydroxylation.^{5,6} The spinel-type phase can have both AI_{0} and AI_{T} coordination environments, depending on the degree of inversion.^{3,7} The chemical shift for AI is sensitive to the second nearest neighbor (NN) coordination sphere; AIO_y polyhedra (where y = 4 or 6 for tetrahedral or octahedral coordination, respectively) bonded to Mg (AlO_v-Mg) have second NNs with a lower electron density, and thus experience weaker shielding effects, than those bonded to AI (AIO_v-AI), resulting in larger positive chemical shift values for AlO_y-Mg.⁷ Thus, we would expect Al coordinated in the periclase phase, with a higher degree of Mg second NNs, to result in resonances downfield relative to those in the spinel-type phase, which have a higher degree of Al NNs. This trend is clearly observed for Mg₃Al-ox, which has the lower Al content and the smaller spinel phase fraction, giving the more positive chemical shift values. Alo and Al_T are shielded to differing degrees in Mg₂Al-ox (upfield for Al₀—influenced more by spinel, downfield for Al_T). The absence of peak splitting to represent the distinct coordination environments possible in each phase make further analysis and quantification of the catalytically-relevant periclase phase not possible in these Mg_xAl-ox samples.

Figure S4. XPS analysis on Mg₃Al-ox as a representative sample shows the absence of Na signals near (a) 30 and 63 eV and (b) 1072 eV,^{8,9} indicating no measurable Na⁺ content on the surface.

Figure S5. N₂ adsorption (solid symbols) and desorption (open symbols) isotherms measured at 77K for the Mg_xAl-ox and MgO catalysts. Inset in isotherm for Mg₂Al-ox shows aggregation of platelet-shaped crystallites that give rise to slit-shaped mesopores.

The isotherms for Mg_xAl-ox are of type IV and exhibit type H3 hysteresis, which is consistent with the presence of slit-shaped mesopores that form from the aggregation of platelet-shaped crystallites (SEM image in inset of Fig. S5) during calcination and decomposition of the LDH phase.^{10–12} The MgO sample exhibits a type II isotherm, which indicates that the accessible surface of this oxide is dominated by macroporosity and/or external surface area.¹⁰

Figure S6. DFT pore size distributions calculated from the N₂ adsorption-desorption isotherms (77 K) for (a) Mg_xAl-ox and (b) MgO.

The DFT pore size distributions (PSDs) for Mg_xAl-ox show the presence of mesopores predominantly between 3 and 15 nm in diameter (d_{pore}) as well as micropores with $d_{pore} \sim 1.5$ nm, which form from gaseous CO₂ and H₂O "cratering" through the decomposing layers during calcination.^{13,14} The PSD for MgO shows the presence of a wide distribution of mesopores (d_{pore} between 3 and 35 nm).

Discussion of the results from the CO₂ TPD experiments over the oxide catalysts

Probe molecule TPD experiments are sensitive to several factors, including the sweep gas flowrate, the temperature ramp, and molecular diffusion of the probe through the catalyst pores. These effects preclude precise identification of specific (e.g., weak vs. medium) site types as a function of desorption temperature, but general trends can be observed, and the total site density can be measured. CO_2 desorption from weak and medium strength sites manifests in a broad peak for the Mg_{*}Al-ox samples at lower temperatures. Weak basic sites arise from surface hydroxylation of the metal oxide (M-O) upon dissociative adsorption of H₂O (OH/M^{x+} and H/O²⁻), with the latter hydroxyl group acting as a weak Brønsted base.¹⁵ The larger amount of CO₂ desorption from Mg₂Al-ox compared to Mg₃Al-ox (T ~ 125 °C) suggests the former has a larger density of weakly basic hydroxyl groups. This might originate during the decomposition of the LDH precursors. As the structure decomposes during calcination, interlayer carbonate anions and water molecules react to form gaseous CO₂ and hydroxyl groups to coordinate with octahedral Mⁿ⁺.¹⁶ The density of these charge-compensating carbonates increases with Al content in the LDH phase, resulting in a more hydroxylated environment that can persist even after calcination.¹⁷

Medium strength sites arise from M-O pairs exposed on the {100} surface.⁵ While the site strengths are comparable (i.e., the desorption occurs over the same temperature range) for the Mg_xAl-ox samples, the density of sites with 200 °C < T_{desorb} < 450 °C decreases with increasing Al content. Further, the maximum for the peak corresponding to desorption from weak/medium-strength sites shift to 325 °C over Mg₃Al-ox compared to Mg₂Al-ox (225 °C), indicating a higher density of relatively stronger medium-strength sites over the Mg₃Al-ox sample. This is consistent with the fact that stoichiometric periclase surfaces with more Mg-O domains will have stronger medium-strength, M-O-type basic sites than those with higher degrees of Al coordination, due to the higher electron density on an oxygen coordinated to Mg²⁺ compared to that coordinated to the more electronegative Al³⁺.^{5,18} Additionally, we observe a trend in overall basic character in the decreasing total basic site density with increasing Al content (Table 1).

The lower temperature region in the profile for pure MgO shows distinct desorption events centered around 250 and 325 °C. These basic sites are very similar in nature to those on the Al-substituted oxides: weakly basic hydroxyl groups form from water dissociation on the M-O surface, and medium strength sites arise from surface-exposed M-O pairs. However, the pure MgO is a single phase and has fewer inherent defects (e.g., no heteroatom substitution or tetrahedral occupation), making for a more crystalline structure. This, in turn, yields a narrower distribution of sites compared to the complex coordination environments in the Al-substituted samples.

The peaks at higher temperature (>450 °C) in the Mg_{*}Al-ox and MgO TPD profiles can be attributed to CO_2 desorption from strong sites. Strong basic centers form from low-coordinated O^{2-} , which can have unsaturated bonding due to morphology (e.g., edges or corners) or other defects (e.g., cation vacancies).⁵ It is also possible that some of the desorption at these higher temperatures over the Al-substituted samples arises from the decomposition of remnant carbonates that grafted into the oxide structure during calcination of the LDH phase.¹⁷

Figure S7. DRIFTS spectra of CO₂ adsorbed on Mg_xAl-ox and MgO measured from 50 to 350 °C. Kubelka Munk units = $f(R_{\infty})^{19}$

$$R_{\infty}(T) = \frac{R_{sample}^{CO_2}(T)}{R_{sample}^{He}(T)}$$
$$f(R_{\infty}(T)) = \frac{(1 - R_{\infty}(T))^2}{2R_{\infty}(T)}$$

S9

Figure S8. Acetaldehyde conversion profiles over Mg_xAl -ox and MgO (0.1% acetaldehyde/99.9% N_2 , 10 sccm total flowrate, 10 mg catalyst, 250 °C, 1 bar) show a steep decay indicative of catalyst deactivation. Inset shows the brown color of the spent MgO sample after 4 hr on stream (fresh sample is white). Spent Mg_xAl -ox exhibited similar color changes (not shown).

Figure S9. Full product distributions measured over time for the Mg_xAl-ox and MgO catalysts (0.1% acetaldehyde/99.9% N_2 , 10 sccm total flowrate, 10 mg catalyst, 250 °C, 1 bar).

Ethanol can be produced from acetaldehyde via gas-phase hydrogenation/reduction reactions over metal oxide catalysts (e.g., SiO₂-supported alkali metals,²⁰ faujasite-type zeolites,²¹ MgAl and NiAl oxides,²² TiO₂ surfaces²³) that exhibit basic character. The hydrogen required for this can be produced from the decomposition of acetaldehyde^{22,23} or water²⁴ (generated as a by-product during condensation reactions), or from the formation of heavy carbonaceous deposits (via dehydration and dehydrogenation routes) that form at early time on stream. Other work has suggested that ethanol is produced from acetaldehyde via a Cannizzarro-type disproportionation, despite the fact that this mechanism usually requires a non-enolizable (i.e., lacking α -H) aldehyde.^{25–27} We do not detect the formation of acetic acid, a by-product of a Cannizzarro-type disproportionation, but we do detect trace amounts of acetone that can form from acetate coupling over basic metal oxides.²⁸ Either mechanism could be contributing.

The largest amounts of ethanol were measured over the Mg_xAl-ox catalysts. These catalysts have more acid-strong base pairs than MgO (minimal acidity) that facilitate the formation of ethoxide species from acetaldehyde.^{5,20,23} For Cannizzaro-type disproportionation reactions, these sites facilitate the adsorption (Lewis acid rather than vacancy-mediated), nucleophilic attack, and hydrogen transfer in the proposed mechanism.²⁶

Ethanol can also be produced from the Claisen condensation or hydrolysis of ethyl acetate, which forms from the Tischenko esterification of two acetaldehyde molecules.^{24,29} We detect ethyl acetate formation at early times on stream that has previously been reported to occur over acid-base pairs (increasing with increasing catalyst acidity).^{21,29,30} However, the ethyl acetate yields were not sensitive to CO₂ titration while ethanol yields were (see Fig. S11). If ethyl acetate was an intermediate for ethanol production, we would expect an increase in ethyl acetate yields as ethanol formation activity decreased. Thus, direct hydrogenation/reduction or Cannizzarro-type reactions are responsible for ethanol formation. No major ethanol-derived products were detected in the product stream (e.g., 2-methylbenzyl alcohol, the alcohol analog of *ortho*-tolualdehyde/2-methylbenzaldehyde). The surface coverage of ethanol is likely much less than that of acetaldehyde given that the latter is continuously fed into the reactor, and the residence time is quite short (~10 ms).³¹

Figure S10. Benzene yields over Mg_xAl-ox and MgO with strong basic sites (low-coordinated O^{2-}) titrated by CO₂ (0.1% acetaldehyde/10 % CO₂/89.9% N₂, 10 sccm total flowrate, 10 mg catalyst, 250 °C, 1 bar).

Over untreated MgO (Fig. 4b), the benzene yield peaks within the first 0.5 hr on stream, and then decays to 0. Benzene activity over Mg_xAl-ox samples is negligible (<0.2 mol C%). The low overall activity on all catalysts could be due to unfavorable kinetics (i.e., less favorable than competitive pathways), rapid active site deactivation, and/or low density of active sites. Benzene forms via the cross-condensation of acetaldehyde and 2-butenal (Scheme S2). The C₂ α -enolate formed via base deprotonation (red arrow) adding to the C₄ carbonyl-C is shown, but the same product (2,4-hexadienal) can theoretically be obtained from the C_4 enolate (at the y-C) adding to the C_2 carbonyl-C. Upon dehydration of the aldol, 2,4-hexadienal forms. This cyclodehydrates via a ring-closing mechanism to benzene.²¹ The production of benzene must compete with several other pathways. First, 2,4-hexadienal can be an intermediate to 2,4,6-octatrienal in a cross condensation with acetaldehyde. This would consume 2,4-hexadienal to yield the tertiary aldol product. However, our analysis from the production of the C₈ species indicates that this is likely not a primary factor contributing to the low benzene yields. 2,4-hexadienal is produced through either basedeprotonation of the acetaldehyde α -C or 2-butenal y-C, followed by addition to the carbonyl-C positions on 2-butenal or acetaldehyde, respectively. This addition step (cross-condensation) competes with the same (α -C₂ or γ -C₄) enolates adding to the carbonyl-C positions on acetaldehyde or 2-butenal, respectively, which would form 2-butenal and 2,4,6-octatrienal and/or o-tolualdehyde (selfcondensation). Thus, it is possible the self-condensation routes are more kinetically favorable relative to the cross condensation-route required to form 2,4-hexadienal and ultimately, benzene. Additionally, if the C₂ α -enolate is forming more appreciably than the C₄ y-enolate, the probability of its interaction with the carbonyl-C of acetaldehyde is much higher than that of 2-butenal: a continuous feed of 1000 ppm (0.1%) acetaldehyde is delivered to the reactor.

In-situ CO₂ titration studies, which selectively deactivate basic sites whose temperature of CO₂ desorption exceeds that of the reaction temperature (250 °C), show that strong basic sites are responsible for early TOS benzene activity over MgO. Thus, over MgO, strong basic sites attributed to low-coordinated surface O^{2-} are the responsible sites for benzene formation at early TOS, before MgO promotes other aldol pathways and/or the site deactivates. Deactivation is likely, given the tendency of strong basic sites to produce heavy polycondensation-type products that are nonvolatile at reaction conditions, resulting in fast deactivation due to site blockage.^{32–34} No significant change in benzene activity is detected over the CO₂-titrated Mg_xAl-ox strong sites, which indicates that the low benzene activity on these materials arises from weak and/or medium strength sites. These catalysts and/or reaction conditions are not good candidates for further analysis of benzene formation given the very low overall benzene production.

Scheme S2. Formation of benzene via cross-aldol condensation of acetaldehyde and 2-butenal and cyclodehydration of the 2,4-hexadienal aldol product

Figure S11. Full product distributions measured over time for the *in-situ* CO₂-titrated Mg_xAl-ox and MgO catalysts (0.1% acetaldehyde/10 % CO₂/89.9% N₂, 10 sccm total flowrate, 10 mg catalyst, 250 °C, 1 bar).

In-situ CO₂ titration minimally affects ethyl acetate production, consistent with previous reports that acidbase pairs (rather than low-coordinated O²⁻) are predominantly responsible for the Tischenko esterification of acetaldehyde.^{21,22,29,30} Ethanol production (particularly at early time on stream) is also affected, because of the influence of the strong sites on the intermediates, rather than the actual formation mechanism, involved in ethanol production (similar to the effect of CO₂ pretreatment on tolualdehyde yields). *In-situ* CO₂ titration impacts ethanol formation not because strong O²⁻ sites are responsible (otherwise, we would see complete loss of ethanol production), but because the selective deactivation of these sites thwarts their role in the formation of heavy carbonaceous deposits, the by-product of which is H₂. Decreased gas-phase H₂ then decreases the extent of acetaldehyde hydrogenation/reduction. While strong, low-coordinated O²⁻ sites do participate in certain mechanisms,^{35,36} medium-strength, M-O pairs on MgO surfaces are the active center for the formation of the primary side products (ethanol, ethyl acetate) measured in this study.^{20,21,23,26,29,30} As a result, selective deactivation of strong, O²⁻ sites does not significantly impact the product distribution.

Figure S12. (a) CO₂ DRIFTS spectra from 50 to 350 °C on spent MgO, after 5 hr on stream. Time on stream determined by the time to reach tolualdehyde yields <0.001 mol C%. (b) CO₂ DRIFTS spectra on fresh and spent MgO at 100 °C, zoomed in to 0.02 Kubelka Munk units to more clearly visualize the low-intensity δ (C-OH) mode.

Table S1. Equilibrium distribution of tolualdehyde isomers (ortho- and para-) at 250 °C, 1 ba	r
calculated in ASPEN	

Tolualdehyde isomer	x ^{eq} (mol/mol)
ortho-	0.312
para-	0.688

Results found to be independent of initial molar fraction guess, total concentration of tolualdehydes in gas feed, and reactor module (REquil/RGibbs).

1A: C₂ α-enolate + C₆ carbonyl-C

1B: C₆ α -enolate + C₂ carbonyl-C

Scheme S3. Proposed route 1 ($C_2 + C_6$) cross-condensation subroutes that result in C_8 enals that can mechanistically electrocyclize to tolualdehydes

Figure S13. Base deprotonation (red arrow) at the sp² α -C and the sp³ γ -C can both yield a C₄ α -enolate (i.e., the position of origin for the nucleophilic attack), but the sp² anion is a much less kinetically favorable intermediate given that, unlike in the sp³ anion, the negative charge cannot be stabilized via π -delocalization.^{37,38}

Table S5. Computational details for NBO analysis of the γ-deprotonated 2-butenal enolate intermediate

2-butenal anion

Figure S14. (a) XRD patterns for as-synthesized Al(OH)₃ and γ -Al₂O₃ obtained upon calcination.^{18,39} (b) XRD pattern of the mechanical mixture prepared with MgO and γ -Al₂O₃ with a molar ratio of Mg/Al = 2.

Figure S15. Yields of (a) 2-butenal and (b) tolualdehydes over MgO, Mg_xAl-ox, γ -Al₂O₃, and a mechanical mixture of MgO/ γ -Al₂O₃ (6.13 mg MgO, 3.87 mg γ -Al₂O₃) with molar Mg/Al = 2 (0.1% acetaldehyde/99.9% N₂, 10 sccm total flowrate, 10 mg catalyst, 250 °C, 1 bar).

Figure S16. The *ortho*-tolualdehyde isomeric fraction measured over all catalysts investigated: MgO, Mg_xAl-ox, γ -Al₂O₃, and a mechanical mixture of MgO/ γ -Al₂O₃ (6.13 mg MgO, 3.87 mg γ -Al₂O₃) with molar Mg/Al = 2 (0.1% acetaldehyde/99.9% N₂, 10 sccm total flowrate, 10 mg catalyst, 250 °C, 1 bar).
