Isolation of B-N adduct 8b

The iminopyrrolyl-BPh$_2$ compounds **7**-**10** have been prepared in a straightforward manner, following the procedure described in the main text of this article. However, in one of the preparations carried out in this work for compound **8**, a Lewis acid-Lewis base adduct **8b** (Scheme S1) between the ligand precursor 5-phenyl-2-(N-2,6-diisopropylphenylformimino) pyrrole (**4**) with B(C$_6$H$_5$)$_3$, was formed instead. Crystals suitable for X-ray diffraction enabled the determination of the molecular structure of **8b** (Scheme S1 and Figure S10).

While in **8** the iminopyrrolyl ligand is chelated to the boron atom through the two nitrogen atoms, forming the usual five-membered ring, in the case of **8b** (Scheme S1), the B(C$_6$H$_5$)$_3$ Lewis acid only establishes a coordinative bond between boron and the iminic nitrogen of **4**. The elimination of benzene did not occur in this case, possibly because the ligand precursor Z conformation was *syn* instead of the more thermodynamically stable E (*anti*).[1] This could result via the unlikely direct formation of the Z isomer of ligand precursor **4** (Scheme S1), via umbrella inversion of the planar iminic nitrogen, in the particular (uncontrolled) experimental conditions used in its synthetic condensation reaction. Alternatively, isomerization of the more thermodynamically favoured isomer E to Z could occur in the presence of BPh$_3$, since it is known in the literature[2,3] that E-aldimines can isomerize to their corresponding Z-aldimines in the presence of boranes. The formation of the Z isomer in the adduct, along with the presence of a very bulky 2,6-diisopropylphenyl group, will likely lock the iminopyrrole ring, preventing its rotation about the imino group and the approach of the NH proton to the boron centre, and thus the elimination of benzene.

Fig. S21. Plots of (a) the difference between –IP and HOMO versus the energies of the HOMOs, and of (b) the difference between –EA and LUMO versus the energies of the LUMOs of compounds **7–12**. IP and EA were estimated from cyclic voltammetry measurements, and the energies of the HOMOs and LUMOs were determined by DFT (CH_2Cl_2) and, in the particular case of the LUMOs of compounds **8** and **10**, by DFT (THF).

Electroluminescence studies

A preliminary characterization of the electroluminescent properties was made using neat films of the synthesized molecules **7-10** as emissive layers (Table S5), in two different device structures. The first type was prepared using vacuum thermal deposition, with the following structure: ITO/PEDOT:PSS/Cmpd/Ca/Al. The second type of devices was fabricated by a wet process (spin-coating technique), using an additional hole-transporting/electron-blocking layer of poly(bis-4-butylphenyl-*N*,*N*-bisphenyl)benzidine (polyTPD)) (*ca.* 10 nm). ITO (indium-tin oxide) was used as the anode, PEDOT:PSS (poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate)) (*ca.* 40 nm) as the hole injection layer, calcium (1.5 nm) as cathode protected by an overlayer of aluminium (*ca.* 80 nm). The emissive layer (Cmpd) thickness was within the range 100-110 nm.

Table S5. Characteristics of OLEDs based on complexes **7-12** including maximum luminance (L_{max}, cd.m^{-2}, and voltages at which the maximum value is obtained), external quantum efficiency (EQE_{max}, %, and voltages at which the maximum value is obtained), current efficiency ($\eta_{L_{max}}$, cd.A^{-1}), and Commission Internationale de l'Éclairage (CIE) colour coordinates.

[a] Values from Ref. 5f, with OLED structure: ITO/PEDOT:PSS/Cmpd/Ca/Al (spin-coating); [b] Not available.

Table S5 shows that most of the molecules displayed better results when applied as emissive layers in the second type of organic light-emitting diodes, containing the additional polyTPD hole-transporting layer. In fact, the first devices fabricated with compounds **7-9** exhibited luminance maxima within the range 4.3-1450 cd.m^{-2}, together with external quantum efficiencies maxima up to 0.06 %. Typically, the maximum luminance is recorded before the device breaks down. These results show that the devices based on **7-9** performed better than those from **11** and **12**. These outcomes were enhanced upon insertion of a polyTPD hole-transporting/electron-blocking layer, which is expected to improve

the selective holes migration to the emissive layer, while confining the electrons, and, consequently, increase recombination efficiency. Thus, it was possible to achieve luminance maxima from 301 up to 4140 cd m^{-2} along with external quantum efficiencies maxima of 0.03-0.15 %. However, the opposite result was observed with 2-iminopyrrolyl boron complex **10**, which displayed a better performance in the first type of device. Nevertheless, this molecule exhibited poor device characteristics in both cases (Table S5, Figures S23-S24).

The boron complex **8** also gives good results when applied as neat emissive layer in OLEDs containing a polyTPD hole-transporting layer. In fact, the maximum luminance is higher than that of the OLEDs based on the other two analogues **7** and **10**. The electroluminescence (EL) spectrum of **8**, exhibits a second band between 550 and 700 nm that is not present in neither the solution nor film photoluminescence, which affects the device performance, being possibly related to a degradation process (Figure S22). Supporting evidence for such degradation comes from the fact that when the devices are driven near the limit (maximum voltages) its intensity is increased in an irreversible way.

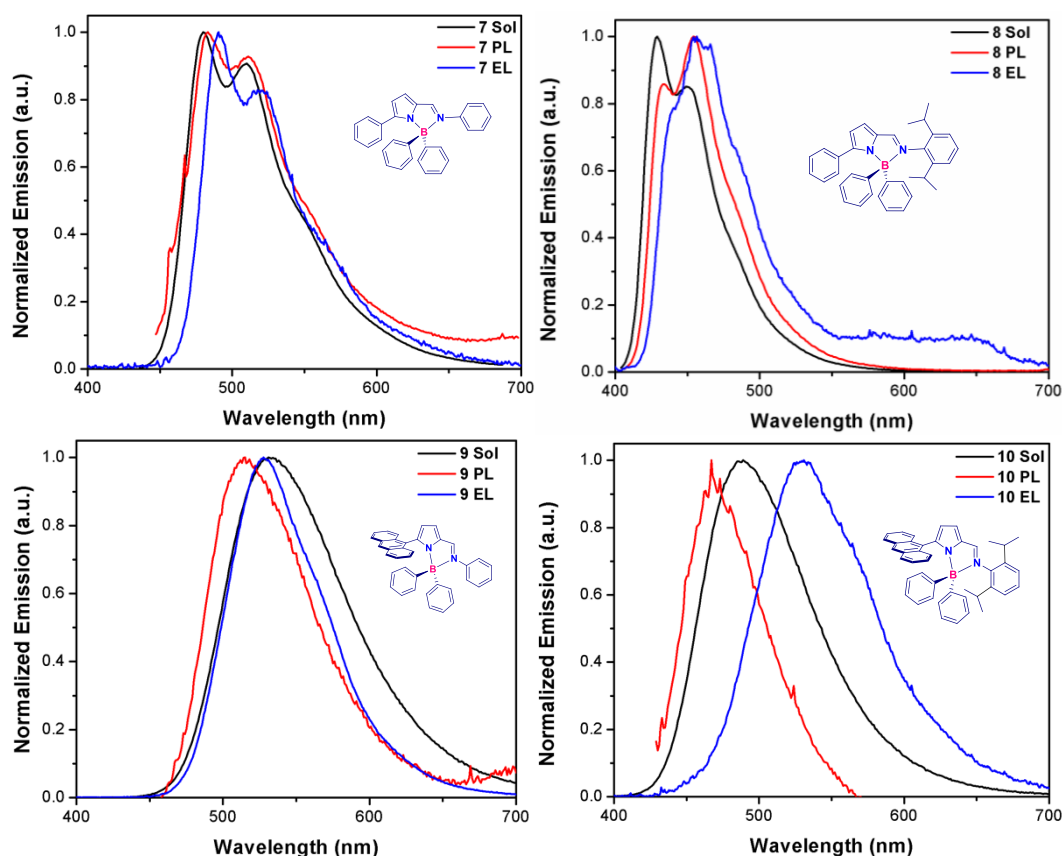

Figure S22. Electroluminescence spectra (EL) of OLED devices containing compounds **7**-**10** as emitters compared to film photoluminescence (PL) and solution fluorescence spectra in THF (Sol).

The recorded EL spectra of compounds **7**, **9** and **10** are also compared with solution fluorescence and film photoluminescence spectra in Figure S22. Compounds **7** and **9** exhibit similar spectra shape and wavelength maxima, proving the inexistence of aggregates formation or degradation processes.

Regarding complex **10**, a red-shifted EL spectrum (531 nm) was obtained in relation to its film PL (470 nm) and solution (489 nm) spectra. Such red-shifted spectrum is common to both device types tested and may indicate that the emissive state generated upon electrical excitation is different from that generated upon photoexcitation. We also find that the electroluminescence spectrum of compound **10** when driven at high voltage, near the limiting value before device break down, is irreversibly modified, indicating degradation. No similar observations were made for either compound **7** or **9**. Further studies are required to clarify the origin of such shift.
