Section 1. Vertical excitation for the adenine monomer and the aqueous $(\mathrm{dA})_{5}$

Table S1. Vertical ( $E_{\perp}, \mathrm{eV}$ ) excitation energies, oscillator strengths (f), dipole moments (D.M., Debye), and state characterizations at the Franck-Condon for the adenine monomer $(\mathrm{A})$ in vacuo and the $(\mathrm{dA})_{5}$ oligomer in a water solvent box. The values in italic for aqueous $d(A)_{5}$ were taken from CAS(14e/10o)/Amber ground state optimizations following by eight roots state average CASPT2 computations and the rest values for vertical excitation of $d(A)_{5}$ were taken from CAS(14e/10o)/Amber ground state optimizations following by seven roots state average CASPT2 calculations.

## Section 2. The relaxation paths in the $S_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} n \pi^{*}\right)$ and $\mathrm{S}_{\mathrm{N} 7 \mathrm{P}}\left({ }^{1} n \pi^{*}\right)$ states.

The relaxation paths of the other two $n \rightarrow \pi^{*}$ transitions for the adenine monomer and aqueous $(d A)_{5}$, originated from promoting lone pair electron of $\mathrm{N} 3\left[\mathrm{~S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)\right]$, and $\mathrm{N} 7\left[\mathrm{~S}_{\mathrm{N} 7 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)\right]$ atoms, were also examined in Figures S 1 and Figure S2. The vertical excitation energy of $\mathrm{S}_{0} \rightarrow \mathrm{~S}_{\mathrm{N} 1 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ transition increases from 4.80 eV for the adenine monomer to 4.91 eV for the aqueous $\mathrm{d}(\mathrm{A})_{5}$ due to the effect of base stacking. In contrast, the vertical excitation energies of $\mathrm{S}_{0} \rightarrow \mathrm{~S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ and $\mathrm{S}_{0} \rightarrow \mathrm{~S}_{\mathrm{N} 7 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ transitions for the aqueous $\mathrm{d}(\mathrm{A})_{5}$ are respectively 0.62 and 0.23 eV red-shifted with respect to those of the adenine monomer in vacuo. This indicates that base stacking exerts negligible influences on the $\mathrm{S}_{0} \rightarrow \mathrm{~S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} n \pi^{*}\right)$ and $\mathrm{S}_{0} \rightarrow \mathrm{~S}_{\mathrm{N} 7 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ excitations and participation of water molecules may play important roles on the red-shifted energy levels of vertical excitations. It is generally accepted that water molecule may impose a polar environment and hydrogen bonds through $\mathrm{H}_{2} \mathrm{~N}^{\cdots} \mathrm{H}-\mathrm{OH}$ or $\mathrm{C}=\mathrm{O} \cdots \mathrm{H}-\mathrm{OH}$ models. One does not expect that a polar environment cause significant influence on the $n \rightarrow \pi^{*}$ transition since it leads to the diradical configuration. However, the formation of hydrogen bond was found to result in the improvement of $n \rightarrow \pi^{*}$ vertical excitation energies about $0.18 \sim 0.43 \mathrm{eV}$ due to the unfavorable influence of mutual attraction on the electron promotion of the lone pair. ${ }^{\mathrm{S} 1, \mathrm{~S} 2}$ Since $n \rightarrow \pi^{*}$ transition excitation energy is not the focus of this work and the use of model hydrogen bond complex unnecessarily complicates the understanding to the photophysics of UV-irradiated DNA, hydrogen bond is not considered in the present

Figure S1. Illustrative relaxation path for the ground state recovery of (a) an aqueous (dA) $)_{5}$; and (b) an adenine monomer in the gas phase; starting from the FC point of the $\mathrm{S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ state along the RC defined by dihedral angle C4N3C2H2.
work. The decay of the $\mathrm{S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} \mathrm{n}^{*}\right)$ state through the structural deformation of the $\mathrm{C} 2-\mathrm{H} 2$ bond twisting is shown in Figure S 1 (a). With increased dihedral angle C 4 N 3 C 2 H 2 , the singly occupied orbitals gradually shows some CT $\pi \rightarrow \pi^{*}$ transition character, which is sensitive to the polarity of the water solvent. This is another reason why a relative large red-shifted vertical excitation energy of the $\mathrm{S}_{0} \rightarrow \mathrm{~S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} \mathrm{n}^{*}\right)$ transition is found from adenine monomer in vacuo to aqueous $\mathrm{d}(\mathrm{A})_{5}$. It also explains the dipole moment change ( $\Delta=1.27$ Debye) in FC region as compared with that of $\mathrm{S}_{0} \rightarrow \mathrm{~S}_{\mathrm{NIP}}\left({ }^{1} \mathrm{n} \pi^{*}\right)(\Delta=$ 0.27 Debye ). Keeping in mind that the previous computational and experimental studies are mostly concentrated on the lowest lying $\mathrm{S}_{0} \rightarrow \mathrm{~S}_{\mathrm{NIP}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ excitation, the differentiation of all the possible $\mathrm{n} \rightarrow \pi^{*}$ transition patterns in this work will facilitate a better understanding of the complicated excited state dynamics of DNA.

Figures S1 and S2 illustrate respectively the relaxation paths in the $\mathrm{S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ and $\mathrm{S}_{\mathrm{N} 7 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ states for the aqueous $(\mathrm{dA})_{5}$ and adenine monomer in the gas phase. The first $n \rightarrow \pi^{*}$ transition corresponds to the lone pair of the N3 atom and the anti-bonding $\pi^{*}$ orbital mainly localized in the six-membered ring, whereas the second corresponds to the lone pair of the N 7 atom and the anti-bonding $\pi^{*}$ orbital mainly localized in the five-membered ring. The vertical excitation energy of the $\mathrm{S}_{0} \rightarrow \mathrm{~S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} n \pi^{*}\right)$ transition is red-shifted from 5.96 eV for the adenine monomer to 5.34 eV for the aqueous $(\mathrm{dA})_{5}$. The initial decay starting from the FC point of $\mathrm{S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ is accompanied by an elongation in the $\mathrm{C} 2-\mathrm{N} 3$ bond from 1.328

Figure S2. Illustrative relaxation path for the ground state recovery of (a) an adenine monomer in the gas phase; and (b) an aqueous (dA) $)_{5}$, starting from the FC point of the $\mathrm{S}_{\mathrm{N} 7 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ state; along the RC defined by the dihedral angle C5N7C8H8.
$\AA$ to $1.438 \AA$ with a single bond character at the $175^{\circ} \mathrm{C} 4 \mathrm{~N} 3 \mathrm{C} 2 \mathrm{H} 2$ twisting (see Figure S1). This eliminates the structural constraint for the subsequent C2-H2 bond twisting and decreases the energy by 0.813 and 1.316 eV for the aqueous $(\mathrm{dA})_{5}$ and adenine monomer, respectively. As shown in Figure S1 (b), for the adenine monomer the downhill MEP along the $\mathrm{C} 2-\mathrm{H} 2$ bond twisting goes to the conical intersection $\mathrm{CI}\left(\mathrm{S}_{\mathrm{N} 3 \mathrm{P}} / \mathrm{S}_{0}\right)$ at a $90^{\circ} \mathrm{C} 4 \mathrm{~N} 3 \mathrm{C} 2 \mathrm{H} 2$ distortion. For the aqueous $(\mathrm{dA})_{5}$ a small barrier of 0.13 eV is found at a $125 \sim 130^{\circ} \mathrm{C} 4 \mathrm{~N} 3 \mathrm{C} 2 \mathrm{H} 2$ dihedral angle along the MEP in the $\mathrm{S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ state. The barrier increases slightly from the adenine monomer to oligomer, which indicates that base stacking interactions exert negligible influence on the $\mathrm{S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ state decay. The route of the $\mathrm{S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} n \pi^{*}\right)$ state decay through the structural deformation of the $\mathrm{C} 2-\mathrm{H} 2$ bond twisting is a fast channel for the relaxation of the adenine multimer.

The $\mathrm{S}_{0} \rightarrow \mathrm{~S}_{\mathrm{N} 7 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ transition has a higher vertical excitation energy for the isolated adenine (6.29 $\mathrm{eV})$ and aqueous $(\mathrm{dA})_{5}(6.06 \mathrm{eV})$ than other two $\mathrm{n} \rightarrow \pi^{*}$ transitions. Similar to that in the $\mathrm{S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} \mathrm{n}^{*}\right)$ state, the initial decay of the $\mathrm{S}_{\mathrm{N} 7 \mathrm{P}}\left({ }^{1} n \pi^{*}\right)$ state is characterized by an $\mathrm{N} 7-\mathrm{C} 8$ bond elongation, resulting in a more optimal structure for the C8-H8 bond twisting and a sharp decrease in the potential energy (see Figure S2). The subsequent decay for the isolated adenine is dominated by a barrierless pathway through an energy plateau at $\sim 5.30 \mathrm{eV}$ with respect to the zero level of $\mathrm{S}_{0}$ along the RC of the C 8 - H 8 bond twisting. Meanwhile, the ground state energy of the adenine monomer rapidly increases from 2.99 eV at $90^{\circ}$ to 4.55 eV at $85^{\circ} \mathrm{C} 5 \mathrm{~N} 7 \mathrm{C} 8 \mathrm{H} 8$ distortion, and eventually reaches the conical intersection $\mathrm{CI}\left(\mathrm{S}_{\mathrm{N} 7 \mathrm{P}} / \mathrm{S}_{0}\right)$ that lies 4.97 eV above the $\mathrm{S}_{0}$ minimum. In a similar fashion, the $\mathrm{C} 8-\mathrm{H} 8$ bond twisting of the aqueous $(\mathrm{dA})_{5}$ in the $\mathrm{S}_{\mathrm{N} 7 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ state leads to a flat potential, in which a small barrier $(0.10 \mathrm{eV})$ is
found. However, the decreased C5N7C8H8 angle for $(\mathrm{dA})_{5}$ does not result in an energy degeneracy between the $\mathrm{S}_{\mathrm{N7P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ and ground state. The energy gap between these two states of $(\mathrm{dA})_{5}$ is 1.07 eV at a $65^{\circ} \mathrm{C} 5 \mathrm{~N} 7 \mathrm{C} 8 \mathrm{H} 8$ distortion, whereas an energy degeneracy is already reached at an $83^{\circ} \mathrm{C} 5 \mathrm{~N} 7 \mathrm{C} 8 \mathrm{H} 8$ angle for the isolated adenine. This indicates that the $\mathrm{S}_{\mathrm{N} 7 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right)$ state is unlikely involved in the slow ground state recovery for the UV photoexcited adenine multimer.

## Section 3. Computational Details

For the QM/MM interface a hydrogen link-atom scheme was used to saturate the valence of the QM subsystem where the $\mathrm{N} 9-\mathrm{C} 11$ and $\mathrm{N}^{\prime}-\mathrm{Cl1}^{\prime}$ bonds were cleaved. To reduce the strong interaction between the two closest $\mathrm{MM}\left(\mathrm{C} 11, \mathrm{C} 11^{\prime}\right)$ point charges and a link atom, these point charges were set to zero. ${ }^{\text {S3 }}$ To compensate for this some point charges of the MM atoms were re-parameterized, where the modified values are summarized in Table S2. The default point charges were used for the remaining MM part. The QM part of the calculation was done at the CASSCF level of theory with the 6-31G* basis set and an appropriate active space. To describe the ${ }^{1} \mathrm{n} \rightarrow \pi^{*}$ transitions originated from the lone pairs of the $\mathrm{N} 1\left(\mathrm{~N} 1^{\prime}\right), \mathrm{N} 3\left(\mathrm{~N}^{\prime}\right)$ and $\mathrm{N} 7\left(\mathrm{~N} 7^{\prime}\right)$ atoms, the corresponding three $n$ orbitals were included in the active space. Other orbitals came from the $\pi / \pi^{*}$ orbitals of the adenine dimer. Since including all of them will be prohibitively expensive, we excluded some unimportant $\pi$ and $\pi^{*}$ orbitals whose occupation numbers are close to 0 or 2 . This resulted in a total of 14 active electrons in 10 active orbitals (14e/10o). When searching for the relaxation paths some convergence problems were encountered during the excited state optimizations. This was fixed by excluding the n orbitals that correspond to the lowest $\mathrm{N} 1\left(\mathrm{~N} 1^{\prime}\right)$ lone pairs in most cases but are replaced by the $\mathrm{N} 3\left(\mathrm{~N} 3^{\prime}\right)$ and N 7 ( $\mathrm{N} 7^{\prime}$ ) lone pairs when the critical points in the $\mathrm{S}_{\mathrm{N} 3 \mathrm{P}}$ and $\mathrm{S}_{\mathrm{N} 7 \mathrm{P}}$ states were optimized.

Scheme S1. Simple diagram of the QM/MM computational protocol for finding the MEPs of the (dA) 5 oligomer: the QM subsystem includes the middle adenine dimer or trimer; other parts of $(\mathrm{dA})_{5}$, the counterions, and a total of 1933 water molecules in the solvent box are treated as the MM part.

Table S2. Re-parameterized point charges in the QM/MM interface region

| C11 | 0.0 | C11' | 0.0 |
| :---: | :---: | :--- | :---: |

| H11 | 0.194555 | H11 | 0.194555 |

The local minima in different excited states of $(\mathrm{dA})_{5}$ were obtained by unconstrained CASSCF/Amber QM/MM optimizations. The constrained energy profiles for relaxation path were obtained using the two root state-averaged CASSCF/Amber stepwise optimizations along the selected RC. These two roots were taken from the ground state and a corresponding excited state with equal weights. For every stationary point optimization, the RC was fixed at given value while other degrees of freedom were totally relaxed without any constraint. The relaxation paths were preliminary mapped along variant value of reaction coordinates. All solvent water molecules with close distance to $(\mathrm{dA})_{5}$ and direct mutual interaction are totally relaxed during the CASSCF/Amber QM/MM optimizations. To account for the dynamical correlation effects, single-point energies were recalculated with the corresponding second-order perturbation theory (CASPT2) using a five-root state-averaged CASSCF zeroth-order wave function. The $\mathrm{O}(1 \mathrm{~s}), \mathrm{N}(1 \mathrm{~s}) \mathrm{C}(1 \mathrm{~s})$, orbitals were frozen in the core and an IPEA-shift value of 0.0 as well as a shift of 0.2 was used in all CASPT2 computations. The vertical excitation energies, the corresponding oscillator strengths, and the transition dipole moments for the
lowest seven excited states of the $(\mathrm{dA})_{5}$ oligomer were obtained using the ground state $\operatorname{CASSCF}(14 e / 10 \mathrm{o})$ optimizations followed by the seven and eight roots state-averaged CASPT2 and CASSCF state interaction (CASSI) computations. The same computational strategy was used for the calculations of the adenine monomer ( 9 H -adenine). The numbers of roots for the state-averaged CASPT2 calculations were reduced to 6 for the vertical excitation and 4 for the minima, respectively, in the relaxation paths of the adenine monomer. Frequency calculations were carried out to confirm the minima for various excited states of the adenine monomer in vacuo.

The following model procedure was used to define the RC of the relaxation pathway. The $\mathrm{QM} / \mathrm{MM}$ unconstrained minimum optimization of $(\mathrm{dA})_{5}$ with all structural parameters relaxation in the $\mathrm{S}_{\mathrm{stack} 2}\left({ }^{1} \pi \pi^{*}\right), \mathrm{S}_{\mathrm{NIP}}\left({ }^{1} \mathrm{n} \pi^{*}\right), \mathrm{S}_{\mathrm{N} 3 \mathrm{P}}\left({ }^{1} \mathrm{n} \pi^{*}\right), \mathrm{S}_{\mathrm{N} 7 \mathrm{P}}\left({ }^{1} n \pi^{*}\right)$, and the inter-base charge transfer $\mathrm{S}_{\mathrm{CT}}\left({ }^{1} \pi \pi^{*}\right)$ states leads to the twisting motion of the $\mathrm{C} 2-\mathrm{H} 2$ bond, the amino group, the $\mathrm{C} 2-\mathrm{H} 2$ bond, the $\mathrm{C} 8-\mathrm{H} 8$ bond, and the C2-H2 bond, respectively. This indicates these twisting motions are responsible for characteristics of structural deformation induced by specific electron transition pattern in the relaxation of corresponding excited states. To describe these twisting motions, C4N3C2H2, C2N1C6N10 and C5N7C8H8 dihedral angles were respectively assigned as the RC for the structural deformation of the $\mathrm{C} 2-\mathrm{H} 2$ bond, amino group and the C $8-\mathrm{H} 8$ bond. The same structural deformation in the $\mathrm{S}_{\text {stack } 2}\left({ }^{1} \pi \pi^{*}\right)$ state, defined as the " C 2 puckering" or "H2 out of plane motion", was described by changes of the C2N1C4C5 and C6N1C2H2 dihedral angles in the previous literatures. ${ }^{\text {S4-S6 }}$ As discussed in the section of the relaxation of the $\mathrm{S}_{\text {stack } 2}\left({ }^{1} \pi \pi^{*}\right)$ state, the different RC choice does not lead to principal discrepancy for the same type of structural deformation.

## Section 5, Energy tables and Cartesian coordinates of the optimized structures

In this work, we optimized too many structures in various electronic states. If all Cartesian coordinates and relative energies are given in this supplementary information, the file will be very long. As an alternative solution, we made a separated file with all cartesian coordinates and tables with all relative energies for the optimized structures that is available through email xuebochen@bnu.edu.cn from Xuebo Chen upon request.
