6	Cu@SILP3	2.8	0.4	36.2	5.8	35.4	19.7

1.5 Textural properties of SILPs

All the samples of two systems –SILP1-3 and Cu@SILP1-3 – were analysed through low-temperature nitrogen adsorption (T = 77.35 K, ASAP 2020, Micromeritics).

The pore size distribution (PSD) was estimated using three independent methods:

1)   Semiempirical classical Barrett-Joyner-Halenda (BJH) approach based on Kelvin's equation predicting a pressure at which adsorbate will spontaneously condense (and evaporate) in cylindrical pores of a given size. The computation was carried out from the adsorption branch data.

2)   Nguyen-Do method modified by Gun'ko (MND), which consists in the application of the self-consisted regularisation (SCR) under non-negative conditions of the pore size distribution function, i.e. $f(R_p) > 0$ at any pore radius R_p and the set regularisation parameter a = 0,01. For the present computation, the entire desorption branch was chosen. The method allows one to estimate the contributions of different pore types based on their size hierarchy: micropores (V_{micro} at $R_p < 1$ nm), mesopores (V_{meso} at 1 nm $< R_p < 25$ nm) and macropores (V_{macro}, $R_p > 25$ nm) in the distribution function $f_v(R_p)$. The pores were considered as cylinders and voids among particles aggregates.

3)   Nonlocal density functional theory (NLDFT) in the model with the assumption for cylindrical pores using the adsorption branch. Unlike classical thermodynamic macroscopic models, the NLDFT methods describe the behaviour of fluids confined in the pores on a molecular level which allows molecular properties of gases to be related to their adsorption properties in pores of different sizes. It follows that pore size characterisation methods based on the NLDFT approach apply to the whole range of micro- and mesopores. The adsorbed fluid is to be on the tapis in a pore is in equilibrium with a bulk gas phase. It is a general practice to adjust interaction parameters (fluid-fluid and fluid-solid) in such a way that the model would correctly reproduce fluid bulk properties (*e.g.,* bulk liquid-gas equilibrium densities and

pressures, liquid-gas interfacial tensions) as well as standard adsorption isotherms on well-defined non-porous adsorbents. The calculation of pore size distribution is based on a solution of the Adsorption Integral Equation (AIE), which correlates the kernel of theoretical adsorption/desorption isotherms with the experimental sorption isotherm:

$$N\left(\frac{p}{p_0}\right) = \int_{W_{min}}^{W_{max}} N\left(\frac{p}{p_0}, W\right) f(W) dW$$

where $N(p/p_0)$ - experimental adsorption isotherm data; W - pore width; $N(p/p0,W)$ - isotherm on a single pore of width W; $f(W)$ - pore size distribution function.

Specific surface area, S_{BET}, was calculated from the BET method. The total pore volume V_p was estimated at the maximal relative pressure of $p/p_0 \approx 0.98$–0.99 within the MND procedure in parallel to NLDFT and BJH.

The Fowler–Guggenheim (FG) equation was used to describe localised monolayer adsorption with lateral interaction:[1,2]

$$\theta_i(p,E) = \frac{Kp \cdot exp(\frac{zw\Theta}{k_BT})}{1 + Kp \cdot \exp\left(\frac{zw\Theta}{k_BT}\right)}$$

where $K = K_0(T)exp(E/k_BT)$ is the Langmuir constant for adsorption on energetically uniform sites, and the pre-exponential factor $K_0(T)$ is expressed in terms of the partition functions for isolated gas and surface phases, z is the number of nearest neighbours of an adsorbate molecule (assuming $z = 4$), w is the interaction energy between a pair of nearest neighbours, k_B is the Boltzmann constant, e.g., $zw/k_B = 380$ K for nitrogen. This equation is used as a local isotherm, ϑ_1, in the overall adsorption isotherm equation, Θ, to calculate the distribution function $f(E)$ of the adsorption energy:

$$\Theta(T,p) = \int_{0}^{E_{max}} \theta_i(T,p,E) f(E) dE$$

where Θ is the experimental amount adsorbed. A maximum $p/p0$ value corresponds to nearly monolayer coverage $\Theta = a/a_m \sim 0.99$ [3]. This calculation was performed on the CONTIN-based software. [4,5]

The geometric topography of the surface structure of nanomaterials can be characterised by the fractal dimension D_S, which is a kind of roughness exponent. The determination of the surface roughness can be investigated using the modified Frenkel-Halsey-Hill (FHH) method, which is

applied in the range of multilayer adsorption.[6–8]

Hence, the estimation of nanoxide fractality was performed on the basis of the FHH method, which can be applied in the range of multilayer adsorption. For this purpose, the adsorption branch within $p/p_0 < 0.8$ values have been used, where the capillary condensation occurs in mesoporous SILPs. The fractal dimension D_S was being calculated from the plot corresponding to the following equation proposed by Avnir and Jaroniec:[9]

$$\ln(V/V_0) = (D_S - 3) \cdot \ln[\ln(p_0/p)] + const$$

where V, V_0 is the adsorbed volume of N_2, the saturation volume of adsorbed N_2, respectively, p and p_0 are the equilibrium and saturation pressure of nitrogen adsorbed, respectively.

2.5 DFT method validation and Model Cluster

The computational method employed was selected according to a validation procedure based on empirical properties of the Cu_2 dimer[16] such as diatomic bond distance (*r*), Dissociation Energy (D_e), vibrational frequency (*f*), Vertical ionization potential (VIP) and the Electronic Affinity (EA). Calculations were performed with the relativistic pseudopotential and basis set LANL2DZ[17]. The functionals tested were PBE[18], BP86[19], OLYP[20] and M06L[21]. Table S9 summarizes the results obtained from the different functionals. The results indicate that lower average error is performed by the PBE functional with 6.02% of error with respect to the reference values. The worst performance was obtained from OLYP with a 13.73% of error, while, the meta-GGA functional M06L present an average error of ~10%. Considering these results, the functional selected to carry out the theoretical study is PBE.

Table S8. Summary of the results obtained from the calculation of r, D_e, f, VIP, EA, and their average error compared to experimental values extracted from[16].

Functional	r (Å)	D_e (eV)	f (cm^{-1})	VIP (eV)	EA (eV)	Error (%)
PBE	2.24	2.34	263	8.01	0.74	6.07

BP	2.23	2.36	267	8.14	0.92	6.62
OLYP	2.30	2.07	231	7.58	0.45	13.73
M06L	2.21	2.60	282	7.77	0.76	9.45
Exp.	2.22	2.01	264	7.90	0.83	-
