Experimental

A known flow of helium ($500\text{--}1200 \text{ cm}^3 \text{ min}^{-1}$; 99.999%, Coregas) is passed through a copper tube ($\sim 3 \text{ m}$), and a measured flow of neutral reagent ($1 - 10 \mu\text{L hr}^{-1}$) is injected *via* a septum downstream from a gas tight syringe using a syringe drive (Pump 11 Elite, Harvard Apparatus). The helium pressure regulator that controls the flow of helium into the ion trap under normal operating conditions is bypassed, and instead the helium pressure is controlled manually by matching the pressure in the vacuum chamber surrounding the ion trap ($2 \times 10^{-5} \text{ Torr}$), measured using an ion gauge, to that under normal operating conditions. The injection port and subsequent, coiled copper tubing is heated to about $20 - 30^\circ\text{C}$ above the boiling point of the corresponding neutral to ensure efficient vaporisation of the reagent into the helium flow. This is achieved by applying a variable voltage (0 - 260V) to heating tape wrapped around the copper tubing (Powertech Variac SRV – 5).

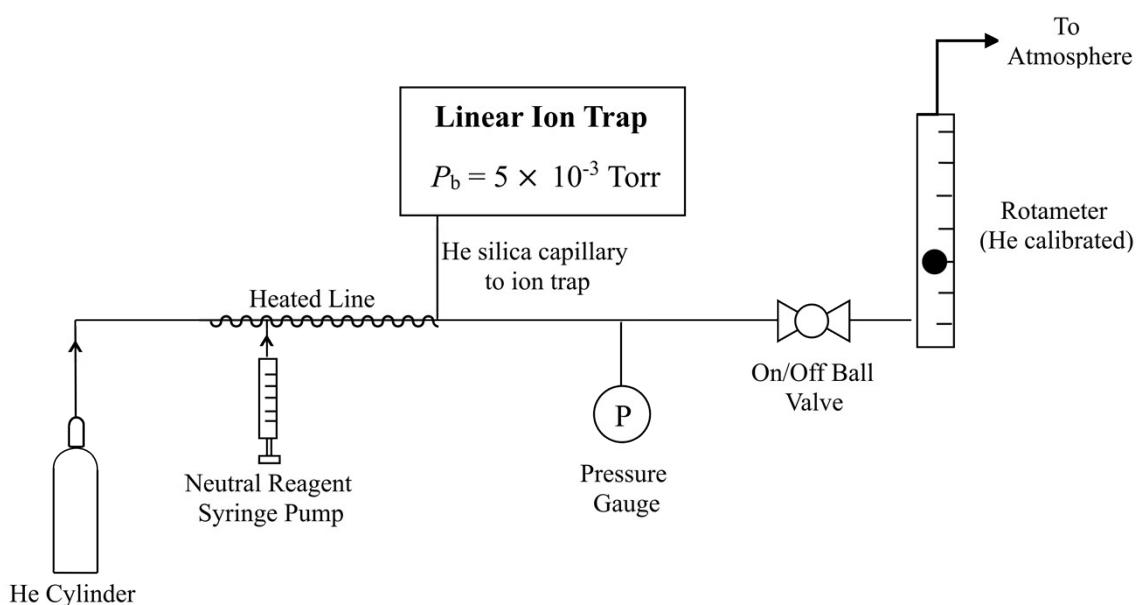

Figure S1. Schematic of apparatus utilized to add neutral reagents to the ion trap for ion-molecule reactions *via* the helium gas line.

The composition of this external mixture is calculated using the known molar flow rates of helium and neutral reagent. A small fraction of this mixture is carried through a silica capillary into the ion trap, whilst the remainder exits through a flowmeter (P single flow tube rotameter, He calibrated, Aalborg) allowing variation of the helium flowrate. The restriction capillary maintains the pressure of the ion trap at $P_b = 5 \times 10^{-3} \text{ Torr}$ in the region where IMR occur.¹ This mixture of helium and neutral reagent effuse out of the ion trap into the vacuum manifold and since the lighter helium atoms effuse more rapidly and are lost at greater rate, then the steady-state solution of the differential equations describing the molar flow of neutral reagents about the ion trap (i.e. the “flux” of neutral reagents) allows the equilibrium pressure of neutral reagents, P_n (Torr), to be calculated (Eq. S1).² Once an appropriate flow of this mixture was established, the reagent pressure was allowed to equilibrate (typically 1 – 2 hours) prior to kinetic measurements.

$$P_n = P_b \times \frac{molar\ flow\ rate\ of\ neutral}{molar\ flow\ rate\ of\ helium} \times \sqrt{\frac{molar\ mass\ of\ neutral}{molar\ mass\ of\ helium}}$$

Eq. S1

Theoretical Collision Rates – Average Dipole Orientation (ADO) Theory

The ADO rate, k_{ADO} , is dependent on the charge of the ion (q), the reduced mass of the reactants (μ), the polarizability (α) and permanent dipole moment (μ_D) of the neutral, and can be calculated according to the following equation S2:

$$k_{ADO} = (2\pi q/\mu^{1/2})[\alpha^{1/2} + C\mu_D(2/\pi kT)^{1/2}], \quad \text{Eq. S2}$$

where C has been parametrized to have a value between 0 and 1 with the expression $\sqrt{\mu_D/\alpha^{1/2}}$. Experimental data has been used for the polarizability and permanent dipole moment where available, but the polarizability has not been measured for *cis*-cyclooctene (Table S1). Instead, this quantity has been calculated from the atomic hybrid polarisabilities (ahp) using the additivity method discussed by Miller,³ with comparison included for cyclohexene.

Table S1. Experimental permanent dipole moments (μ) and comparison of experimental and calculated polarizabilities (α) for cyclohexene and *cis*-cyclooctene

Major products included: π -ligand exchange (m/z 231), addition-elimination of HI (m/z 131), and addition-elimination of H_2 (m/z 257). The latter peak arises due to the feasibility of benzylic stabilization of the charge in the initial addition adduct with subsequent elimination of H_2 introducing additional allylic stabilization. m/z 207 is styrene addition to a styryl cation followed by H_2 elimination.
