Materials and Reagents

FeCl$_3$·6H$_2$O and urea were purchased from Aladdin Industrial Corporation. KOH and Na$_2$SO$_3$ were purchased from Sinopharm Chemical Reagent Co., Ltd. Co(NO$_3$)$_2$·6H$_2$O, Ni(NO$_3$)$_2$·6H$_2$O, and sodium citrate were purchased from Tianjin Guanghua Technology Development Co., Ltd. Deionized (DI) water (18.2 MΩ cm) used in this work was obtained from a Molecular Lab water purifier. Before the experiments, fluorine-doped tin oxide-coated glass (FTO, < 15 Ω sq$^{-1}$, Nippon Sheet Glass Co., Ltd.) was cut into 1 × 2.5 cm and was ultrasonically cleaned with acetone, ethanol and DI water for 20 min each. All reagents above were analytical grade and were used without further purification.
Characterizations

The morphology of all photoanodes were characterized by a field emission scanning electron microscopy (SEM; Hitachi S-4800). Transmission electron microscopy (TEM) and high-resolution TEM (HRTEM) associated with an X-ray energy-dispersive spectrometer (EDS) were analyzed on a Tecnai G²Tf20 transmission operated at 200 kV. The crystallization was studied by the X-ray diffraction spectra (XRD), conducted on a Rigaku D/max-2400 diffractometer with the X-ray source of Cu Kα radiation and data were collected in Bragg–Brentano mode with a scan rate of 0.2° s⁻¹ in the range of 10°-90°. The surface bonding information was analyzed by X-ray photoelectron spectroscopy (XPS) measurements, operated on a Kratos Axis Nova X-ray photoelectron spectrometer with a monochromated Al Kα X-ray source, operating at 15 kV and 10 mA and referenced to the C 1s peak (284.8 eV). Raman spectra were researched Via Renishaw confocal spectroscopy with 633 nm laser excited, and the sample side of photoanode faced the laser source. The light absorption abilities of all samples were measured with UV/Vis absorption spectra (Hitachi U-4000) with BaSO₄ as the reference.

Photoelectrochemical (PEC) measurements

The PEC measurements of all photoanodes were achieved on the CHI760E electrochemical workstation (CH Instruments Co.) in a standard three-electrode system, which containing the photoanodes (WE), a Pt fossil (1 × 1 cm², CE), a saturated Ag/AgCl electrode (RE). All PEC measurements were performed in the 1 M KOH electrolyte (PH=13.6), and the effective work area of the photoanodes was adjusted to 1 cm× 1 cm². A 300 W xenon arc lamp (Perfect Light solar simulator) equipped with an AM 1.5 G filter was employed as the light source, and the light intensity on the electrode surface was adjusted to 100 mW cm⁻² (1 sun illumination). Linear sweep voltammetry curves were obtained with a scan rate of 5 mV s⁻¹ in the potential range of 0.5 V~1.6 V vs. RHE. A monochromator was utilized to measure the incident photon-to-current efficiency (IPCE) with a 300 W Xe lamp as the
simulated light source. Mott-Schottky (M-S) curves were gained at the
dark condition and with a fixed frequency of 1 kHz with a scan rate of
20 mV⁻¹. Electrochemical impedance spectroscopy (EIS) was obtained at
a 1.23 V vs. RHE under light with an ac voltage amplitude of 5 mV over
a frequency range from 10⁻¹ to 10⁶ Hz, and was fitted by ZView software.

Equations in this work

1. The measured potential was converted to the reversible hydrogen electrode (RHE) using the Nernst equation:

   \[ E_{RHE} = E_{Ag/AgCl} + E^0_{Ag/AgCl} + 0.0591 \times pH \]  

   Where \( E_{RHE} \) is the converted potential vs. RHE, \( E_{Ag/AgCl} \) is experimentally measured potential against Ag/AgCl reference electrode, and \( E^0_{Ag/AgCl} = 0.1976 \) V (vs. Ag/AgCl) at 25 °C.¹

2. Calculation of the Applied bias photo-to-current conversion efficiency (ABPE)

   Assuming 100% Faradaic efficiency, the ABPE was obtained by the following equation:

   \[ ABPE (\%) = \left( J \times (1.23 - E_{app})/P_{light} \right) \times 100\% \]  

   Where \( J \) is the measured photocurrent density (mA cm⁻²), \( E_{app} \) is the applied potential (V vs. RHE) and \( P_{light} \) is the incident illumination power density (100 mW cm⁻²).

3. Calculation of the Incident photo-to-electron conversion efficiency (IPCE):

   \[ IPCE(\%) = \left( (J_{mono} \times 1240) / (\lambda \times P_{mono}) \right) \times 100\% \]  

   where \( J_{mono} \) is the measured photocurrent density at the specific measurement wavelength (mA cm⁻²), \( \lambda \) is the incident light wavelength (nm) and \( P_{mono} \) is the measured irradiance at the specific measurement wavelength (mW m⁻²).

4. Electrochemical double layer capacitance (Cdl)

   The electrochemically active surface area (EASA) was estimated from the electrochemical double-layer capacitance. Cyclic voltammograms were performed at
the scan rate of 20, 40, 60, 80, 100, 120, 140, 160, 180, 200 mV s\(^{-1}\) (Fig. S8). Then the EASA was determined by measuring the capacitive current associated with double-layer charging from the scan-rate dependence of CVs. The double layer capacitance (C\(_{dl}\)) was estimated by plotting the \(\Delta J = (J_a - J_c)\) at 1.23 V vs. RHE against the scan rate as shown in Fig. 3d, where \(J_a\) and \(J_c\) are the anodic and cathodic current, respectively. The linear slope is twice of the C\(_{dl}\), which can be used to represent the EASA.\(^2\)

5. Mott-Schottky measurement

M-S plots were collected at an AC frequency of 1kHz in the dark, and the N\(_D\) of the photoanodes could be estimated by the following equation:

\[
N_D = \frac{2}{\varepsilon_0 \varepsilon \kappa} \left( \frac{1}{C^2} \right) \int \frac{dV}{J} \quad \text{equation S4}
\]

Where \(C\) is the space charge capacitance in the semiconductor (obtained from M-S curves), \(e\) is the electron charge, \(\varepsilon\) is the vacuum permittivity (8.85\(\times\)10\(^{-12}\) F m\(^{-1}\)), \(\varepsilon_0\) is the relative dielectric constant of hematite (\(\varepsilon_0 = 80\)), \(N_D\) is the charge donor density (cm\(^{-3}\)), \(V\) is the electrode applied potential, \(V_{fb}\) is the flat band potential, \(\kappa\) is the Boltzmann’s constant (1.38\(\times\)10\(^{-23}\) J K\(^{-1}\)) and \(T\) is the absolute temperature (K). It should be noted that the capacitance (\(C\)) is based on a flat structure, and therefore it is not suitable for our non-flat structure of the one-dimensional geometry nanorod arrays. In general, the comparison results of the flat structure and non-flat structure show that an underestimate of the donor density by 20% is achieved for the latter mode when it is considered as the former one. In this work, all the Fe\(_2\)O\(_3\)-based nanoarrays photoanodes are non-flat structure, thus the \(N_D\) values for them are 20% larger than the experimental results calculated by equation.

6. Light harvesting efficiency (LHE)

LHE is defined as the fraction of photons absorbed per photons impinging on the sample, which could be calculated using the following equation:

\[
LHE = 1 - 10^{-A(l)} \quad \text{equation S5}
\]
A(λ) is the absorbance at a specific wavelength.

7. Theoretical maximum photocurrent density (J_{abs})

Theoretical maximum photocurrent density (J_{abs}) is the photocurrent density assuming that all absorbed photons can be converted into current (i.e., APCE = IPCE/LHE = 100%), it is a constant with the AM 1.5G spectrum and the light harvesting efficiency of the fixed photoelectrode. In the case of J_{abs}, it can be calculated according to the following equation:

\[
J_{abs} = \int_{\lambda_1}^{\lambda_2} \frac{\lambda \times LHE(\lambda) \times P(\lambda)}{1240} d(\lambda)
\]

where \( \lambda \) and \( P(\lambda) \) are the light wavelength (nm) and the corresponding power density (mW cm\(^{-2}\) nm\(^{-1}\)) for the standard solar spectrum AM 1.5G (ASTMG-173-03), respectively.

8. The surface charge injection efficiency (\( \eta_{\text{surface}} \)) and bulk charge separation efficiency (\( \eta_{\text{bulk}} \))

Photocurrent density arising from PEC water oxidation can be described by the following equation:

\[
J_{H_2O} = J_{abs} \times \eta_{\text{bulk}} \times \eta_{\text{surface}}
\]

\( \eta_{\text{bulk}} \) is the yield of photo-induced holes which have migrated to the semiconductor/electrolyte interfaces and \( \eta_{\text{surface}} \) is the yield of holes which are involved in water oxidation reaction. In this work, we chose the widely used Na\(_2\)SO\(_3\) as the hole scavenger. Moreover, \( \eta_{\text{bulk}} \) and \( \eta_{\text{surface}} \) were calculated according to the equations, respectively:

\[
\eta_{\text{bulk}} = \frac{J_{Na_2SO_3}}{J_{abs}}
\]

\[
\eta_{\text{surface}} = \frac{J_{H_2O}}{J_{Na_2SO_3}}
\]
$J_{Na_2SO_3}$ and $J_{H_2O}$ are the photocurrent densities measured in 1M KOH with and without 1 M Na$_2$SO$_3$, respectively.

9. The transient decay time

The transient decay time of the photoanodes were calculated according to the transient photocurrent curves in Fig. 5c by the following equation:

$$D = \frac{(I_t - I_s)}{(I_m - I_s)}$$  \hspace{1cm} \text{equation S10}

where $I_t$ represents current at time. The transient decay time is defined as the time at which $\ln D = -1$.

Mott-Schottky (M-S) analysis was conducted at a fixed frequency of 1kHz in dark. Donor density ($N_D$) was evaluated from the slopes of the normalized M-S plots by equation S4, and the flat-band potentials were estimated from x-axis intercept. Fig. S10 clearly shows that all photoanodes own the typical positive slopes of n-type semiconductors, with the electrons as the majority charge carriers. The flat-band potentials present a trend of gradual cathodic shift from $\alpha$-Fe$_2$O$_3$ to the target photoanode. The $N_D$ value increases dramatically from $5.14 \times 10^{19}$ cm$^{-3}$ to $1.93 \times 10^{20}$ cm$^{-3}$ after doping with F, suggesting that fluorine anion acts as a promising n-type dopant to largely enhance the carrier concentration of the hematite. After encapsulating F-Fe$_2$O$_3$ with the surface overlayers, the $N_D$ values of the composite photoanodes slightly increase to $2.72 \times 10^{20}$ cm$^{-3}$ and $3.59 \times 10^{20}$ cm$^{-3}$ for F-Fe$_2$O$_3$@Cit-Ni(OH)$_x$ and F-Fe$_2$O$_3$@Cit-Ni$_{0.9}$Co$_{0.1}$(OH)$_x$, respectively.

Fig. S14. (a) UV-visible absorption spectra (inset: J_{abs} of the F-Fe_{2}O_{3}@Cit-Co(OH)ₓ photoanode), (b) LSV curves collected in 1M KOH and in 1M Na_{2}SO_{3} + 1M KOH and (c) bulk charge separation efficiency and surface charge transfer efficiency of the F-Fe_{2}O_{3}@Cit-Co(OH)ₓ photoanode; (d) the comparison of Nyquist plots between the F-Fe_{2}O_{3} and F-Fe_{2}O_{3}@Cit-Co(OH)ₓ photoanodes.
Fourier-transform infrared (FT-IR) spectra of the target photoanode (before and after 4h-stability test) and sodium citrate suggest the existence of citrate anion in F-Fe$_2$O$_3$@Cit-Ni$_{0.9}$Co$_{0.1}$ (OH)$_x$. As shown in Fig. S14, the peaks at 1589 cm$^{-1}$ and 1386 cm$^{-1}$ could be ascribed to the asymmetric vibration and symmetric vibration of COO$^-$ of citrate anion, while the two sharp peaks of 539 cm$^{-1}$ and 460 cm$^{-1}$ are Fe-O stretching and bending peaks of crystalline hematite.
