1. Experiment detail

Catalyst functionalization and synthesis. The introduction of the NH$_2$ groups on carbon surface was realized using the diazonium reaction. $P$-phenylenediamine, Vulcan XC72 and nitric acid were mixed in a flask, sonicating using sonication bath, and then the mixture was heated to 65 °C in oil bath, and finally sodium nitrite solution was added into the mixture dropwise followed by 18 hrs-heating in an oil bath at 65 °C. The same method was applied for SO$_3$H functionalization but replacing $P$-phenylenediamine with sulfanilic acid. After the reaction, the mixture was washed using DI-water and ethanol, then filtered, and dried in a vacuum oven over night at 60 °C. The synthesized functionalized carbons were analyzed using XPS. The XPS results show the existence of NH$_2$ and SO$_3$H groups introduced on carbon surface with covalent bonded (FigS.2). After confirming the covalently bonded NH$_2$ and SO$_3$H groups onto carbon surface, then Pt nanoparticles were loaded by reducing precursor (H$_2$PtCl$_2$) in mixture of ethylene glycol and DI water at 140 °C for 6 hours. Finally, the dispersion was filtered followed by drying overnight in a vacuum oven at 60 °C over night.

USAXS measurement. The X-ray scattering measurements were conducted at beamline 9ID-C at the Advanced Photon Source (APS), Argonne National Laboratory. The samples of inks after sonication were collected into a glass capillary tube (5 mm diameter, NMR testing tube) and sealed with a rubber cap. The sample tubes were mounted in the beamline hutch and exposed to a 21 keV monochromatic X-ray beam. The scattered intensity was collected within a scattering vector range of $10^{-4}$ to 1 Å$^{-1}$ by using a Bonse-Hart camera setup for USAXS and a Pilatus 100 K detector for pinhole SAXS. The background scattering data from the capillary tube filled with the corresponding solvent (n-PA/H$_2$O) was recorded and subtracted from scattering data for each corresponding catalyst ink. The scattering data were analyzed in a modeling macro package Irena for data fitting and simulation on Igor Pro (WaveMetrics, OR) platform.

Cryo-TEM analysis. A 3.0 uL aliquot of the sample was placed on a glow discharged QUANTIFOIL® R1.2/1.3 300 mesh copper grid. It was then plunge-frozen using FEI Vitrobot Mark III with 8 sec blotting at 20 °C. The frozen grid was loaded into 200 kV Thermo Scientific Glacios™ Cryo Transmission Electron Microscope. Low dose images were recorded using Gatan K3 direct electron detector at ×45,000 nominal magnifications (0.88 Å/pixel) with total dose of 45 e/Å$^2$. 
SEM Analysis of catalyst layer (MEA CL pore structure). MEAs of pristine-carbon black, NH$_2$-XC72 and SO$_3$H-XC72 samples were initially coated with a Gatan-J1 epoxy mixture to improve stiffness, placed in a mold filled with an Araldite® 6005, benzyl dimethylamine and docenylic succinic anhydride mixture, out-gassed to remove air at the MEA/epoxy interface, and cured in an oven at 60 °C for 8 hours. The cured molds were microtomed at room temperature and the electron transparent MEA cross-sections less than 70 nm thick were obtained for TEM observation. To acquire the pore morphology in the MEA CL of three catalysts, a focused ion beam (FIB) coupled with scanning electron microscope (SEM) was utilized in a slice and view mode (Fig.S14). The thickness of each slice was controlled at 10nm, while the current of ion beam was controlled at 7.7pA to mitigate ion beam damage. In addition, the accelerating voltage of electron beam is controlled at 5kV for imaging, after each slicing by the ion beam. A global segmentation was first performed, followed by a manual segmentation and 3D reconstruction to achieve a more precise outline of pores in each image.

TEM analysis of ionomer/catalyst interface

The cathode was scrapped lightly with a razor and the resulting powder was ground and dispersed onto a lacy-carbon film supported on a 200 meshes copper grid. The grids were loaded into a Thermo Scientific Krios G4 cryo-TEM at room temperature, after which the instrument was cooled to cryogenic temperatures. Low-dose, high resolution images were acquired using a Thermo Scientific Falcon 4i direct electron detector with an accelerating voltage set to 300kV.

ITC Measurement

Binding experiments were conducted using a NanoITC (TA Instruments) as previously described$^1$. Briefly, ionomer samples are dialyzed in deionized water and then diluted to 3.25 mg/mL for binding to SO$_3$H-XC72 and XC72 and diluted to 2.75 mg/mL for binding to NH$_2$-XC72 due to the stronger affinity. Ionomer is titrated into a cell containing 0.5 mg/mL nanoparticle in deionized water. For each experiment, an initial 4 uL ionomer aliquot is injected to remove bubbles; this injection is excluded from the data analysis. Twelve 8 uL aliquots of ionomer were injected into the cell at 25°C, with 900 seconds between the start of each injection. Backgrounds were collected (water into nanoparticle, ionomer into water, and water into water) to subtract heats of dilution/mixing from the results. Each injection peak is then integrated, and the heats are fit to an independent binding isotherm using the NanoAnalyze software (TA Instruments). The association
constant is extracted from the model fit, and error bars are obtained from the confidence interval of
the fit.

Surface energy measurement

The surface energy of three carbons with water was measured using the dynamic vapor sorption
(DVS) analysis (Micrometrics, Georgia, US). A sample was held at each temperature to reach
equilibrium while the mass change of the sample was measured at each temperature (RH). The
mass change at each temperature (RH) step was recorded to generate a water vapor sorption (WVS)
curve. The water spreading pressure, liquid-solid adhesion work and the surface energy can be
extrapolated from the WVS curves\textsuperscript{2,3}.

RDE test

All electrochemical measurements were performed using a Biological VSP potentiostat equipped
with high-speed rotators (MSR-RDE-E5) from Pine Instruments (Pine Research Instrumentation,
Durham, NC). A rotating disk electrode (RDE) from Pine Research Instrumentation was used as
the working electrode with a glassy carbon disk: OD = 5.61 mm. A standard hydrogen reference
electrode (S.H.E) ET070 (eDAQ Inc, Springs, CO) and a platinum spring counter electrode
(99.99%, AFCTR5, Pine Research Instrumentation, Durham, NC) was used in a three-electrode
electrochemical cell. To prepare the working electrode, 5 mg catalyst was dispersed ultrasonically
in a 5 mL mixture of isopropanol and DI-water to form an ink. The ink was then drop-casted on the
surface of the glassy carbon disk with a designated loading of 20 µg\textsubscript{Pt} cm\textsuperscript{-2} and dried at room
temperature to yield a uniform thin-film electrode. All the cyclic voltammetry (CV) and ORR
polarization curves were recorded in 0.1 M HClO\textsubscript{4} (70 wt.%, double distilled, VERITAS, GFS
Chemicals, Powell, OH, USA) and the ORR activity was measured in 0.1 M HClO\textsubscript{4} saturated with
O\textsubscript{2} at 1600 rpm using linear sweep voltammetry (LSV) polarization plots at a scan rate of 10 mV
s\textsuperscript{-1}.

MEA fabrication. MEA was prepared using the catalyst coated membrane (CCM) method where
the catalyst ink was directly sprayed onto the proton exchange membrane (Gore® 10 µm) sitting on
a hot plate at 70 °C. Active geometric area of MEA is 5 cm\textsuperscript{2}, 3.51 cm x 1.42 cm. For comparison,
identical anode catalyst layers were prepared with Pt loading of 0.1 mg\textsubscript{Pt} cm\textsuperscript{-2} (±0.01) using 20wt.%
Pt-XC72 (Jiping®, Shanghai, China) with 0.45 I/C ratio through same CCM method mentioned
above. For the cathode, except for the catalyst difference, all conditions were the same including
Pt loading, I/C ratio, and the solvents. The Pt loadings of cathode was controlled to 0.107 mg\textsubscript{Pt} cm\textsuperscript{-2}
(±0.01) The MEA was assembled with Sigracet® 22BB gas diffusion layer (GDL) (SIG, Germany).
**MEA testing protocols.** Differential flow field cell (Figure S13) was applied for MEA testing. MEA was tested using fuel cell testing station (850e, Scribner Associate, Southern Pines, NC) at 80 °C, 100% RH, with flow rate of anodic (H₂) and cathodic (air) in 500 standard cubic centimeter per minute (sccm) and 2000 sccm, respectively under 150 kPa<sub>abs</sub> for both sides. Testing protocols from the US Department of Energy (DOE) were used. MEA was tested by scanning voltage from 0.35 V to open circuit voltage (OCV) with 50 mV/step and holding 60s for each point, the corresponding current density was taken by averaging the values in last 15 seconds. Mass activity (MA) measurement follows the DOE protocol at 80 °C and 100 % RH under pressure of 150 kPa<sub>abs</sub>. The anodic flow (H₂) and cathodic flow (O₂) are 500 sccm and 2000 sccm, respectively. The MA was obtained by holding the cell voltage at 0.6 V for 5min, then, holding voltage at 0.9V <i>r</i>-<i>F</i>ree for 15 min and taking the average value of current in last 5 min, which was recorded every second.

**Limiting Current testing protocol.** Limiting current testing of a MEA was conducted in a differentia cell following the polarization curve test. The reactants are H₂ and the mixture of 2 vol.% of O₂ in N₂ for anode and cathode, respectively, with flow rates of 500/2000 sccm. The current density was first measured at 0.1 V, 0.15 V, 0.2 V and 0.3 V by holding at certain voltages for 2 min and record the average of current value in last 15 s. The limiting currents measured at 0.1 V were used for total O₂ diffusion resistance calculation. The limiting current density and <i>R<sub>total</sub></i> relationship is shown as in the Eq. S1, where <i>F</i> is Faraday constant, 96485 C/mol, <i>x<sub>dry-in</sub></i> is mole fraction of oxygen in dry mass, <i>i<sub>lim</sub></i> (A) is limiting current. The total O₂ diffusion resistance under different pressure was recorded and calculated. Then, the O₂ diffusion resistance was plotted against the pressure. The pressure independent resistance was obtained from the intercept of the plots<sup>4</sup>. In order to distinguish the gas phase O₂ diffusion resistance in catalyst layer <i>R<sub>CL,gas</sub></i> and the O₂ diffusion resistance through the ionomer film, <i>R<sub>CL,ion</sub></i>, the limiting current density difference in relative humidifies (RHs) was measured.<sup>5</sup>

\[
R_{total} = \frac{4Fx^{dry-in}_{O}p-p_w}{i_{lim}RT} \quad \text{Eq. S1}
\]

For the limiting current measured in low relative humidity (RH), after polarization curve measured, the cathode gas was controlled to 20% RH, and MEA was purged under N₂ for both sides’ electrode for 16 hours, then the limiting current density test followed the exact protocol as mentioned above.

**O₂ diffusion resistance calculation.** The O₂ diffusion resistance was calculated using the equation listed below.
\[ R_{\text{CL,ion}} = \frac{\delta_{\text{ion}}^{\text{eff}} H_{\text{ion},O_2}}{A_{\text{ion}}^{\text{eff}} D_{\text{ion},O_2} RT} \]  
Eq. S2

\[ \Psi_{\text{ion},O_2} = \frac{D_{\text{ion},O_2}}{H_{\text{ion},O_2}} = 3.27 \times 10^{-15} \exp[1.28(RH)] \times e \]  
Eq. S3

\[ R = 8.3145 \left( J \cdot \text{mol}^{-1} \cdot \text{K}^{-1} \right) \]

\[ R_{\text{total}} = R_{\text{DM}} + R_{\text{CL, \text{gas}}} + R_{\text{CL, ion}} \]  
Eq. S4

Since \( R_{\text{DM}} \) and \( R_{\text{CL, \text{gas}}} \) are constant for a given electrode, then

\[ R_{\text{RH1}}^{\text{total}} - R_{\text{RH2}}^{\text{total}} = R_{\text{CL,ion}}^{\text{RH1}} - R_{\text{CL,ion}}^{\text{RH2}} \]  
Eq. S5

Eq. S3 could be reduced to \( \Psi_{\text{ion},O_2} = a \times \exp[1.28(RH)] \) under given temperature. Where \( a \) is constant, defined in Eq. S6.

\[ a = 3.27 \times 10^{-15} \times \exp\left[17,200 \left( \frac{1}{R} - \frac{1}{T} \right) \right] \left( \text{mol} \cdot \text{s}^{-1} \cdot \text{m}^{-1} \cdot \text{Pa}^{-1} \right) \]  
Eq. S6

\[ \Psi_{\text{ion},O_2} = a \times \exp[1.28(RH)] \]  
Eq. S7

For all MEAs were tested under 353 K, thus, \( a \) is constant for these cases. Then, combining Eq. S2, Eq. S5 and Eq. S7, we have Eq. S8 as below.

\[ R_{\text{RH1}}^{\text{total}} - R_{\text{RH2}}^{\text{total}} = R_{\text{CL,ion}}^{\text{RH1}} - R_{\text{CL,ion}}^{\text{RH2}} = \frac{q}{\Psi_{\text{ion},O_2}^{\text{RH1}} RT} - \frac{q}{\Psi_{\text{ion},O_2}^{\text{RH2}} RT} = . \]  
Eq. S8

\[ q \left\{ \exp\left[ -1.28(RH_1) \right] - \exp\left[ -1.28(RH_2) \right] \right\} \]  
\[ \frac{RTa}{\Psi_{\text{ion},O_2}^{\text{RH1}} RT} - \frac{RTa}{\Psi_{\text{ion},O_2}^{\text{RH2}} RT} \]

Reorganize the Eq. S8, then, \( q \) becomes Eq. S9
\[ q = \left( \frac{R_{RH1}^{total} - R_{RH2}^{total}}{\exp[-1.28(R_{RH1})] - \exp[-1.28(R_{RH2})]} \right)RTa \]  

Eq. S9

Given

\[ b = \left( \frac{RTa}{\exp[-1.28(R_{RH1})] - \exp[-1.28(R_{RH2})]} \right) \]  

Eq. S10

Where \( b \) is constant under the given temperature and the RH difference.

Substitute Eq. S10 into Eq. S9, then, the Eq. S11 is obtained,

\[ q = \left( R_{RH1}^{total} - R_{RH2}^{total} \right) b \]  

Eq. S11

Under a given temperature and \( RH_1 \) and \( RH_2 \), e.g., 80% RH and 20% RH at 353 K, \( b \) is constant.

Then \( q \) is proportional to the difference, \( \left( R_{RH1}^{total} - R_{RH2}^{total} \right) \).

The \( q \) for three MEAs are named as \( q_{NH2} \), \( q_{Blank} \) and \( q_{SO3H} \). Here we use \( q_{NH2} \) as baseline to calculate the ratio between \( q_{NH2} \) and \( q_{Blank} \), \( q_{NH2} \) and \( q_{SO3H} \):

\[ \frac{q_{Blank}}{q_{NH2}} = \frac{\delta_{eff_{Blank}}^{ionNH2}}{\delta_{eff_{Blank}}^{ionNH2}} \times \frac{A_{eff_{Blank}}^{NH2}}{A_{eff_{Blank}}^{NH2}} \]  

Eq. S12

Here, \( A_{eff}^{ion} \) is proportional to Pt surface area \( A_{Pt} \) which is related to ECSA of MEA\(^5\).

\[ \frac{q_{Blank}}{q_{NH2}} \approx \frac{\delta_{eff_{Blank}}^{ionNH2}}{\delta_{eff_{Blank}}^{ionNH2}} \frac{A_{PtNH2}}{A_{PtBlank}} \times \frac{ECSA_{NH2}}{ECSA_{Blank}} \]  

Eq. S13

From Fig. 6, ECSA of \( NH_2 \), Blank and \( SO3H \) MEAs are 53.28, 46.42 and 25.31 m\(^2\)Pt/mgPt, respectively. Then, substitute these values into Eq. S13 to obtain the following.

\[ \frac{q_{Blank}}{q_{NH2}} \approx \frac{\delta_{eff_{Blank}}^{ionBlank}}{\delta_{eff_{Blank}}^{ionBlank}} \frac{ECSA_{NH2}}{ECSA_{Blank}} \times 0.87 \]  

Eq. S14

\[ \frac{q_{Blank}}{q_{NH2}} \approx \frac{(R_{RH1}^{total} - R_{RH2}^{total})_{Blank}}{(R_{RH1}^{total} - R_{RH2}^{total})_{NH2}} = 0.05656 \]  

Eq. S15

Then:
\[
\frac{q_{Blank}}{q_{NH_2}} = \frac{0.05656}{0.02448} \approx \frac{\delta_{eff}^{Blank}}{\delta_{eff}^{NH_2}} \times 0.87
\]

Eq. S16

Finally, we have the ratios of effective thickness of ionomer films for both pairs as below.

\[
\frac{\delta_{eff}^{Blank}}{\delta_{eff}^{NH_2}} \approx 2.66
\]

Eq. S17

\[
\frac{\delta_{eff}^{SO_3H}}{\delta_{eff}^{NH_2}} = 12.90
\]

Eq. S18

Figure S1. Schematic of (a) catalyst ink drying process, (b) ionomer film and related O2 diffusion resistances.
2. Additional results and discussion

Catalyst particle size distribution

TEM images of CLs from tested MEAs are shown Figure S2. The Pt NPs distribution was shown in Figure S2d. Although the average particle sizes of three Pt NPs are similar, there are few particles from SO₃H catalyst are larger than 6 nm in diameter, suggesting that there are still some large Pt NPs for SO₃H functionalized carbon supports, suggesting that the negatively charged carbon may not facilitate the uniform distribution of Pt NPs. But this small particle size difference is not sufficient to altering MEA performance in this work.

Figure. S2. Transmission electron microscope (TEM) images and Pt nanoparticles distributions of (a) Pt/V\textsubscript{NH₂}, (b) Pt/V, and (c) Pt/V\textsubscript{SO₃H} catalysts; (d) particles size distributions of Pt/V\textsubscript{NH₂}, Pt/V and Pt/V\textsubscript{SO₃H} catalysts (~150 counting)
controlling the ionomer and catalyst interaction than the surface energy does. However, the reality is opposite, the MEA performance at the same RH interval did not show such a trend. This contradiction suggests that the electrostatic force here, plays a more dominant role in because the high hydrophilicity should result in small O₃H carbon, suggesting that SO₃H and NH₂ groups were successfully covalent-grafted on XC72-SO₃H and XC72-NH₂ carbons, respectively. However, no sulfur and nitrogen elements were detected on blank carbon.

**Supplementary Table I.** Summary of Figure. S3.

Besides, after functionalization, the surface energy of functionalized carbons regard to water is changed, from 87.44 mJ·cm⁻² of Blank to 110.2 mJ·cm⁻² and 230.5 mJ·cm⁻² of NH₂ functionalized and SO₃H functionalized carbons, respectively (Supplementary table II). The surface energy of SO₃H is the largest among the three carbons, suggesting that SO₃H carbon is the most hydrophilic one. Assuming the same ionomer coverage among three types of CL, for a certain RH interval (e.g., 20% - 80% RH), the difference of O₂ diffusion resistance of SO₃H CL should have been the smallest because the high hydrophilicity should result in small O₂ diffusion resistance at low RH than others. However, the reality is opposite, the MEA performance at the same RH interval did not show such a trend. This contradiction suggests that the electrostatic force here, plays a more dominant role in controlling the ionomer and catalyst interaction than the surface energy does.

**ITC raw data and fitted data.**

To calculate entropic and enthalpic contributions to binding, it is necessary to use a molar basis. Molar concentrations are calculated following the procedure as previously reported$^1$. As the molecular weight or the polydispersity of the ionomer are not precisely known, the monomer molar concentration is calculated from the mass concentration and equivalent weight. For example, 3.25 mg/mL of 720 EW Aquivion is calculated to be 4.514 mM. The mole of catalyst binding sites is calculated using the surface area of particles—based on density of Vulcan XC72 (264 kg/m$^3$) and primary particle size (50 nm diameter)—and the projected area of ionomer aggregate (assuming a 3 nm x 10 nm cylinder)$^6$. For 0.5 mg/mL XC72, the concentration is calculated to be 0.054 mM. Thermodynamic parameters are extracted from the binding model using this molar basis. Specifically, the extracted binding constant is related to the free energy by (Δ$G$ = RTln[KA]). Using the enthalpic contribution from the isotherm, entropic contributions are calculated using Δ$G$ = Δ$H$ – TΔ$S$.

MEA performance in Helox and different RH

The Helox (21 vol% O₂ in He) test of three MEA is performed with same testing protocol as the air performance of MEA. The performance comparison is shown in Figure S7.

Figure. S8. Performance comparison in Helox and air testing of (a) NH₂ catalyst, (b) Blank catalyst, and (c) SO₃H catalyst. (d) Summary of performance gained in helox test of three MEAs.
The performance of three MEAs in different RHs is shown in Figure S7. NH2 MEA performance is monotonically increasing with RH, and so does the blank MEA. However, for the SO3H MEA, the performance is monotonically increasing with RH except for RH above 80%. SO3H MEA performance at 100 % RH is lower than that at 80%. It is due to the high surface energy of SO3H catalyst so that under saturate condition, in high current density range (e.g., > 2 A cm⁻²), water flooding happens. Under these circumstances, the use of limit current density data at 80 % RH for calculating O₂ diffusion resistance is more reliable.
Figure. S10. MEA performance under 20%, 35%, 50%, 65%, 80%, and 100% RH of (a) Pt/V$_{\text{NH}_2}$, (b) Pt/V, (c) Pt/V$_{\text{SO}_3\text{H}}$ catalysts (0.1mg$_{\text{Pt}}$ cm$^{-2}$) (H$_2$-air fuel cell I-V polarization curves recorded under 150 kPa$_{\text{abs}}$ of air pressure); (d) Pt/V$_{\text{NH}_2}$ (H$_2$-air fuel cell I-V polarization curve recorded under 250 kPa$_{\text{abs}}$ of air pressure); (e) MEA performance under 100% RH of the Pt/V$_{\text{NH}_2}$, H$_2$-O$_2$ fuel cell I-V polarization curve recorded under 150 kPa$_{\text{abs}}$; (f) MEA performance of Pt/V$_{\text{NH}_2}$ with 1.5/2 stoic for H$_2$/air, the geometric of MEA is 25 cm$^2$.
