Calculation methods

Monomer conversion was calculated following eq. 1 from the crude reaction mixture. $\int_{H(\text{polymer})}$ equals the integration of the polymer backbone peak, $\int_{H(\text{monomer})}$ the peak integration of the vinyl proton of the monomer.

$$\text{conversion} = \frac{\int_{H(\text{polymer})}}{\int_{H(\text{monomer})} + \int_{H(\text{polymer})}} \times 100 \% \quad (1)$$

The calculation of the theoretical molecular weight ($M_{n, \text{theory, NMR}}$) is based on the conversion using eq. 2:

$$M_{n, \text{theory, NMR}} = \left(\frac{c_{\text{monomer}}}{c_{\text{CTA}}} \times \text{conversion} \times M_{\text{monomer}} \right) + M_{\text{CTA}} \quad (2)$$

where c_{monomer} and c_{CTA} are the initial concentrations of monomer and CTA. M_{monomer} and M_{CTA} indicate the molecular masses of monomer and CTA. "Livingness" was determined with following eq. 3:

$$L = \frac{c_{\text{CTA}}}{c_{\text{CTA}} + 2fc_i(1 - e^{-k_d t})\left(1 - \frac{f_c}{2}\right)} \times 100 \quad (3)$$

where c_{CTA} and c_i are the initial concentrations of CTA and initiator. The expression "2" refers to the formation of two primary radicals with a certain efficiency f from one initiator molecule. The expression "2" refers to the formation of two primary radicals from one initiator molecule with a certain efficiency f , which is typically 0.5 for diazo-initiators. The resulting chain number at radical termination is given as "1- $f_c/2$ ", where f_c is the coupling factor. k_d describes the decomposition coefficient of the initiator, while t is the reaction time.

$M_{n, \text{UV-Vis}}$ was determined using a Specord 210 spectrophotometer. by using Beer-Lambert eq. 4:

$$A = \frac{\varepsilon d c_{\text{mass}}}{M_{n, \text{UV-Vis}}} \quad (4)$$

where A is the absorption, ε the extinction coefficient, d the optical path length and c_{mass} the concentration. $\frac{\varepsilon d}{M_{n, \text{UV-Vis}}}$ represents the slope, which results in the calculation of $M_{n, \text{UV-Vis}}$ with the following eq. 5:

$$M_{n, \text{UV-Vis}} = \frac{\varepsilon \times d}{\text{slope}} \quad (5)$$

The average hydrodynamic radius and therefore the diameter of the formed aggregates were derived from the Stokes-Einstein eq. 6:

$$r = k_B T / 6\pi\eta D \quad (6)$$

where k_B is the Boltzmann's constant, T the absolute temperature, η the dynamic viscosity and D the diffusion coefficient.

Table 1. Analytical data of pHPMA **10**.

Monomer	Conversion	Polymer	$M_{n, \text{theory, NMR}}$	$M_{n, \text{NMR}}$	$M_{n, \text{UV-Vis}}$	$M_{n, \text{SEC}}^a$	PDI
10	75 %	9	7.8 kDa	38.7 kDa (DP: 267)	38.2 kDa (DP: 263)	9.1 kDa	1.66
