Chemical Details of Polyethylenimine:

Polyethylenimine is a low to high molecular weight polymer with a monomer unit of –[CH₂-CH₂-NH₂]⁻. PEI is available as linear, branched as well as in dendrimer structures. Linear PEI is obtained via ring-opening polymerization of 2-ethyl 2-oxazoline followed by hydrolysis whereas, branched PEI is synthesized via acid-catalyzed polymerization of aziridine. Linear PEI contains only primary amines, however, branched PEI consists of primary, secondary as well as tertiary amines in the ratio of 1:2:1. PEI is a cationic polyelectrolyte with a charge depending on the pH of the dispersion. The Schematic of PEI is shown in Fig. S1.
**Figure S1:** Schematic of the branched structure of polyethylenimine.

In the present case, branched PEI of molecular weight 0.8kg/mol, having a zeta potential of +3.8 mV at pH of 10.5, was used for the preparation of samples.

**Fourier transform of High-Resolution FESEM images**

![Fourier transform images](image)

**Figure S2:** Fast Fourier Transform (FFT) of FESEM images for silica and silica-PEI microspheres. (a) HS40 (b) HS40-PEI (5). Arrows are for the sake of clarity to indicate the low Q region (blue). High intensity in b) refers to the formation of clusters whereas low intensity in a) depicts the uniform jamming in silica-PEI microspheres.
**Figure S3**: Fast Fourier Transform (FFT) of FESEM images for silica-PEI microspheres. (a) HS40-PEI (20) (b) HS40-PEI (33). Arrows are for the sake of clarity to indicate a low Q region (blue). The presence of the high-intensity region indicates the presence of nanoparticle clusters.

**Line Plot Analysis of High-Resolution FESEM images**
**Figure S4:** Profile plot of the electron microscopy high-resolution images of silica and PEI incorporated silica shown in Figures S1 and S2.

**SAXS data for HS40-PEI(50) microspheres from Lab-based X-ray Source**

![Graph showing SAXS data for HS40-PEI(50) microspheres. A solid line shows the model fit to the data.]

**Figure S5:** SAXS Profiles of HS40-PEI(50) microspheres. A solid line shows the model fit to the data.

**Size distribution of HS40 microspheres obtained from fitting of SAXS data**

![Graph showing size distribution of HS40 microspheres.](image-url)
**Figure S6:** Particle Size distribution of virgin silica colloids obtained using the model fit of SAXS profiles. Maxima in particle size distribution represents the average radius of silica nanoparticles.

**Estimation of Specific Interface area between jammed silica nanoparticles: Calculation of the composite density**

Let’s take \( m \) mass of silica microspheres then \( \text{PEI}(x) \times m \) is the mass of the PEI, where \( x \) is the polymer concentration.

Let \( V_s \) and \( V_p \) be the volume of the silica nanoparticles and PEI respectively, which is given as

\[
V_s = \frac{m}{d_s \times \phi_s} \quad \text{and} \quad V_p = \frac{\text{PEI}(x) \times m}{d_p}
\]

(a)

\( d_s \) and \( d_p \) are the densities of the silica nanoparticles and PEI, respectively.

\[
\phi_s = \frac{m}{d_s \times \phi_s} \quad \text{and} \quad \phi_p = \frac{\text{PEI}(x) \times m}{d_p}
\]

Therefore,

(b)

\( \phi_s \) and \( \phi_p \) are the volume fractions of the silica microspheres and PEI. \( \phi_s \) is the volume fraction of the silica obtained through the model fitting of SAXS profiles.

Hence, Composite density, \( d_c = d_s \times \phi_s \times \varphi + d_p \times \phi_p \)

(c)

The interfacial area between the jammed nanoparticles in the solid nano-adsorbent from the fitting parameters of SAXS profiles can be calculated using the equations below:
\[
\frac{\Sigma}{d_c} = \frac{\left[ \lim_{q \to \infty} I(Q)Q^4 \right]}{2\pi d_c (\Delta \rho)^2}
\]

(d)

\[
Q_{\text{inv}} = \int_0^{\infty} I(Q)Q^2 dQ = 2\pi^2 \phi_s (1 - \phi_s) \Delta \rho^2
\]

(e)

\[
\frac{\Sigma}{d_c} = \frac{\pi \phi_s (1 - \phi_s) \left[ \lim_{q \to \infty} I(Q)Q^4 \right]}{Q_{\text{inv}} d_c}
\]

(f) Where, \(\Sigma/d_c\) is specific surface area (m\(^2\)/g), \(\phi_s\) is the volume fraction of silica nanoparticles and \(d_c\) (g/cm\(^3\)) (eq. (c)) is the density of PEI-silica microspheres \(\lim_{q \to \infty} I(Q)Q^4\) is the Porod constant obtained from the Porod plot \(I(Q)Q^4\) vs. Q) of the SAXS data of HS40-PEI microspheres at different loading of PEI, Fig. S7a. The high-Q region in the Porod plot tends to horizontal asymptote indicating sharp interfaces whereas the bell shape of the Kratky plot \(I(Q)Q^2\) vs. Q), Fig. S8 suggests that the \(Q_{\text{inv}}\) integral is converging.

Figure S7: (a) Porod plot for the pure silica and PEI- functionalized silica. Data is shifted vertically for the clarity purpose. (b) Non-monotonic behaviour of the peak position with variation in the concentration of PEI.
Figure S8: Kratky plot for pure silica and PEI-functionalized silica. Data is shifted vertically for a clear presentation. (b) The Low Q region is subtracted.

**BET (Brunauer-Emmett-Teller) and BJH (Barrett, Joyner, and Halenda) analysis of N₂ adsorption isotherms:**

BET (Brunauer-Emmett-Teller) theory is applied to calculate specific surface area using N₂ gas adsorption. BET equation is given as:

\[
\frac{1}{v(p/p_0 - 1)} = \frac{1}{v_m c} + \frac{c - 1}{v_m c} \frac{p}{p_0}
\]

\[(g)\]

Here, \(v\) is the number of molecules adsorbed at a given temperature. \(v_m\) is the number of gas molecules/atoms required to form a monolayer on a solid surface. \(p_0\) is the saturation pressure and \(p\) is the equilibrium pressure of the nitrogen gas at 77K.

\[
\frac{1}{v(p/p_0 - 1)} Vs. \frac{p}{p_0}\]

gives a straight line with
\[ v_m = \frac{1}{\text{slope} + \text{intercept}} \quad c = 1 + \frac{\text{slope}}{\text{Intercept}} \]

(h)

Therefore, the total surface area and specific surface area is given by

\[ S_{\text{Total}} = \frac{sN_A v_m}{V} \quad S_{\text{BET}} = \frac{S_{\text{Total}}}{a} \]

(i)

Where, \( s \) is the adsorbing cross-section of silica microspheres, \( N_A \) Avogadro’s number and \( a \) is the mass of the silica nanoparticles.

BJH (Barrett, Joyner, and Halenda) method\(^2\) is employed to calculate pore size distribution using adsorption-desorption isotherm by utilizing the Kelvin equation, given as

\[ r_K = \frac{-2\sigma v_1}{RT \ln \left( \frac{p}{p_0} \right)} \]

(j)

Here, \( r_K \) is the Kelvin radius. \( \sigma \) and \( v_1 \) are the surface tension and molar volume of the liquid condensate, respectively. \( R \) is the gas constant and \( T \) is the temperature.

The Kelvin radius obtained from eq. (j) determines the pore radius and the film thickness of the adsorbed multilayer obtained using standard isotherms as:

\[ r = r_K + t \]

(k)

Multimodal Peak Analysis of Pore volume distribution:
Figure S9: Multimodal to monomodal peak analysis of (a) HS40 (b) HS40-PEI(11) (c) HS40-PEI(33) (d) HS30-PEI(50) microspheres.

Zeta potential measurements:

The pH of the dispersions for all loading of PEI was measured at ~10. The zeta potential measured for bare silica colloids is estimated to be ~ -45 mV whereas the PEI dispersion shows positive zeta potential (~3.8 mV) at pH ~10.5. Due to the presence of a large number of amine groups, the surface charge of PEI is positive. The zeta potential of silica colloids is negative with the magnitude of negative charge decreasing as the concentration of PEI is increased.
Figure S10: (a) Zeta potential for 2wt% HS40-PEI dispersion with the variation in the concentration of PEI. (b) SANS data for 1 wt% HS40 for different concentrations of PEI.

Calculation of potential amine sites:
**Figure S11**: Potential amine sites over silica-PEI microspheres as a function of PEI loading.

Wang et al. calculated the potential amine sites for the PEI loaded in the sorbent removing the contribution from the surface silanol groups consuming the part of the loaded PEI. However, in the present case, PEI is adsorbing on the silica nanoparticles via electrostatic attraction therefore, the modified formula to calculate amine sites in a sorbent is given as:

\[
P_{\text{potential}} \left( \frac{\text{mol}}{\text{g}} \right) = Wt\% \text{ of the PEI in the sorbent} \times \frac{n}{M_{\text{w,PEI}}} \tag{I}
\]

Here, \(M_{\text{w,PEI}}\) is the molecular weight of PEI, 0.8 kg/mol and \(n\) is 18, the number of amine groups in each PEI chain.

**\(\text{CO}_2\) capture capacity with the variation in temperature**

**Modelling of CO₂ adsorption isotherms**

**Langmuir Model:**

The Langmuir model describes the adsorption on a homogeneous surface by monolayer formation⁴. The assumptions considered by the Langmuir model: 1) adsorbate should be energetically homogeneous, 2) one site occupies one adsorbed molecule, and 3) adsorbed molecules should not have lateral interaction. Therefore, the Langmuir model of adsorption isotherm is described as⁵:

\[
q_e = \frac{q_L k_L p}{1 + k_L p} \tag{m}
\]
Here, $q_L$ (mmol/g) is the adsorption capacity of the monolayer, $p$ (bar) is the pressure and $k_L$ (bar$^{-1}$) represents the affinity constant related to the energy of the adsorption. Furthermore, a dimensionless parameter ($R_L$), known as the separation factor, defined by Weber and Chakarvorti$^6$, is represented as:

$$R_L = \frac{1}{1 + K_L p}$$  \hspace{1cm} (n)

Separation factors indicate the adsorption nature to be linear ($R_L=1$), irreversible ($R_L=0$), unfavourable ($R_L>1$), or favourable ($0<R_L<1$).

**Sips Model:**

The Sips model has three parameters, which is a combination of both the Freundlich and Langmuir models. Sips model is suitable for envisaging adsorption on the heterogeneous surfaces following the homotattic patch approximation (HPA), described as$^5$:

$$q_e = \frac{1}{m_S} \frac{q_S(k_s p)^{m_S}}{1 + (k_s p)^{m_S}}$$  \hspace{1cm} (o)

Here, $k_S$ (bar$^{-1}$) is the affinity, $m_S$ is the heterogeneity factor. A value of $m_S$ near to 1 represents the homogenous adsorption sites where $m_S < 1$ represents the possession of heterogeneous adsorption sites by the adsorbent$^5$. When $m_S$ equals to 1, the Sips model is reduced to the Langmuir model.

**Freundlich Model:**

Freundlich model follows homotattic patch approximation (HPA), proposed by Ross and Olivier$^7$, where the adsorbent’s heterogeneous surface is sub-divided into finite homogeneous
patches, each having different site energy forming the energy distribution function over the surfaces. Therefore, an empirical equation is used to describe the Freundlich model, which is reported as\(^5\):

\[
q_e = k_f p^n \quad n = \frac{-\Delta H_{ad}}{RT}
\]  

Here, \(q_e\) is the CO\(_2\) capture capacity (mmol/g), \(k_f\) (mmol g\(^{-1}\) bar\(^{-1/n}\)) is the constant of the Freundlich isotherm, \(p\) is the pressure (bar) and \(n\) represents the deviation from the linearity of the adsorption. \(n\) indicates the relative distribution of the energy and heterogeneity of the adsorption sites and predicts the favourability of the adsorption. \(\Delta H_{ad}\) (kJ/mol) is the heat of adsorption, \(R\) (8.314 J mol\(^{-1}\) K\(^{-1}\)) is the universal gas constant; \(T\) (K) is the temperature.

**Table S2**: Parameters of the Freundlich, Langmuir and Sips isotherms for CO\(_2\) adsorption of silica-PEI microspheres at different loading of PEI and at different temperatures.
