1. Experimental Section

1.1 Syntheses of Materials

Hydrochloric acid (HCl, 37%), ethanol, potassium hydroxide (KOH), aniline (99.5%), nickel(II) nitrate hexahydrate (NiCl$_2$·6H$_2$O, 99.995%), chloroplatinic acid hexahydrate (H$_2$PtCl$_6$·6H$_2$O, Pt ≥37.5%), and ammonium persulfate (APS, (NH$_4$)$_2$S$_2$O$_8$, 99.99%) were purchased from Aladdin. While Pt/C (20 wt% of Pt on Vulcan XC72) and Nafion (5 wt%) were obtained from the Fuel Cell Store. All the chemical reagents used in this work were analytical grade, and they were utilized directly without any purification. In a typical synthesis procedure of PtNi-NC-900, 9 mL of concentrated hydrochloric acid was added to 14 mL of deionized water, which was stirred to cool down naturally to room temperature. Afterwards, 2 mL of aniline was added dropwise into the diluted hydrochloric acid solution to obtain mix solution A. Then, 2.5 g of APS was dissolved into 10 mL of deionized water, resulting in solution B. Both the solutions were cooled to 4 °C in a refrigerator. Next, the solutions A and B were mixed and maintained at 4 °C for 12 h, which undertook polymerization to form polyaniline. The obtained product was washed with deionized water to pH ≈ 7 and collected by vacuum filtration. 0.3 mmol NiCl$_2$·6H$_2$O and 0.2 mmol H$_2$PtCl$_6$·6H$_2$O were dissolved in 20 mL of deionized water under magnetic agitation for 15 min, and then the collected polyaniline was dispersed in the above solution by stirring for another 1 h. After aging for 2 h, the solution was frozen using liquid nitrogen, then dried by lyophilization. The collected solid was transferred into a porcelain boat and heated (5 °C min^{-1}) to 900 °C under a N$_2$ flow in a tube furnace, then annealed at 900 °C for 2 h, thereby giving the final product of PtNi-NC-900. For comparison, PtNi-NC-800 and PtNi-NC-1000 were also prepared by the similar procedures through controlling the pyrolysis temperatures at 800 and 1000 °C, respectively. Meanwhile, Pt-NC-900 was synthesized by the same method with the absence of NiCl$_2$·6H$_2$O, and NC-900 was prepared by direct pyrolysis of polyaniline at 900 °C for 2 h in N$_2$ atmosphere.

1.2 Materials Characterizations

Scanning electron microscopy (SEM) images were taken on a Zeiss Sigma 300 filed-scanning electron microscope (FE-SEM). Transmission electron microscope (TEM) images, high-resolution TEM (HRTEM) images, selected area electron diffraction (SAED), and elemental mappings were obtained on a Tecnai G2 60-300 HOLO transmission electron microscope (TEM) with an image corrector and an energy-dispersive X-ray spectroscopy detector. X-ray diffraction (XRD) patterns were collected on a X'Pert PRO MPD X-ray diffractometer with Cu Kα radiation. N$_2$ adsorption-desorption isotherms were recorded on a Tristar 3000 surface area and pore analyzer. X-ray

photoelectron spectroscopy (XPS) data were obtained on a Thermo Scientific K-Alpha X-ray photoelectron spectrometer equipped with a monochromatic Al Kα source.

1.3 Electrochemical Measurements

The electrochemical properties of obtained powdery catalysts were investigated in a standard three-electrode system by the rotating disk electrode (RDE) method on a CHI 760E electrochemical workstation. Firstly, the as-prepared sample was dispersed in a mixed solution consisting of deionized water, ethanol, and 5 wt% Nafion by a volume ratio of 10:9:1 under sonication for 1 h. 10 μL of the catalyst ink (4.0 mg mL^{-1}) was then transferred onto a glassy carbon RDE (diameter = 5 mm, Pine Research Instrumentation), which was dried naturally in the air to serve as the working electrode. A carbon rod, a Hg/HgO electrode, and 1.0 M KOH aqueous solution were employed as the counter electrode, reference electrode, and electrolyte, respectively. During the electrochemical testing, the working electrode was rotated at 1600 rpm and a flow of N_2 was maintained to remove H_2 bubbles formed on the RDE surface. All potentials were referenced to a reversible hydrogen electrode by adding a value of (0.098 + 0.0592×pH), and all polarization curves were calibrated by considering the *iR* contribution within the cell.

1.4 Computation Methods

The spin-polarized density functional theory (DFT) calculations were carried out using the Vienna Ab initio Simulation Package (VASP) software.[1, 2] To be specific, PtNi$_3$(111) and Pt(111) slab models were built based on the HRTEM results and element content analysis, representing the catalytic surfaces of PtNi-NC-900 and commercial Pt/C catalysts, respectively. According to the experimentally observed Tafel slope values of PtNi-NC-900 and 20% Pt/C, it can be inferred that the alkaline HER processes on PtNi$_3$(111) and Pt(111) surfaces are much more likely to follow the Volmer-Heyrovsky mechanism that generally involves four steps, namely, the adsorption of water molecule on the active site to form *H_2O, the dissociation of *H_2O to generate *H and *OH, the subsequent desorption of *OH, and the final desorption of *H to release gaseous H_2.[3, 4] All computations were performed using the projected augmented wave (PAW) method and Perdew-Burke-Ernzerhof (PBE) exchange-correction functional to describe the core electrons and the electron interactions, respectively, under the generalized gradient approximation (GGA) with a plane-wave cut-off energy of 600 eV.[5-7] Dispersion correction was also considered in Grimme's scheme using DFT-D3 method.[8] For the geometry optimization, the top two layers of atoms were relaxed completely, whilst the bottom two layers of atoms were fixed. A Γ-point-centered

Monkhorst-Pack k-point grid of 4×4×1 was adopted to sample the Brillouin zone. The energy and force convergence thresholds were set to be 1×10^{-5} eV and 0.02 eV Å^{-1}, respectively. For the calculations of density of states, the k-point grid was increased to 12×12×1. A vacuum space of 15 Å was created in the c direction to avoid interactions between mirror images.

Under alkaline conditions (e.g., 1.0 M KOH, pH = 14), the HER via the Volmer-Heyrovsky mechanism involves the following steps:[3, 4]

$$* + H_2O \rightarrow *H_2O \tag{1}$$

$$*H_2O \rightarrow *H + *OH \tag{2}$$

$$*H + *OH + e^- \rightarrow *H + OH^- \tag{3}$$

$$*H \rightarrow * + 1/2\ H_2 \tag{4}$$

To calculate the free energy diagrams, the concept of computational hydrogen electrode proposed by Nørskov et al. was adopted, that is, the chemical potential of the $(H^+ + e^-)$ couple equals to 1/2 H_2 at pH = 0 in the electrolyte and 1 bar of H_2 in the gas at 298.15 K.[9] Therefore, the reaction free energy of each elementary step above can be calculated by the following equation:

$$\Delta G = \Delta E + \Delta ZPE - T\Delta S + \Delta G_{pH} \tag{5}$$

where ΔE is the electronic energy difference directly available from the DFT computation, ΔZPE is the correction in zero-point energies (ZPE), T is the room temperature (here $T = 298.15$ K), ΔS is the entropy change, ΔG_{pH} is the correction for the H^+ free energy associated with the pH value (i.e., $\Delta G_{pH} = k_B T \times \ln 10 \times pH$, k_B is the Boltzmann constant). Both ΔZPE and ΔS can be obtained from the vibration frequency analysis of the adsorbed species.
