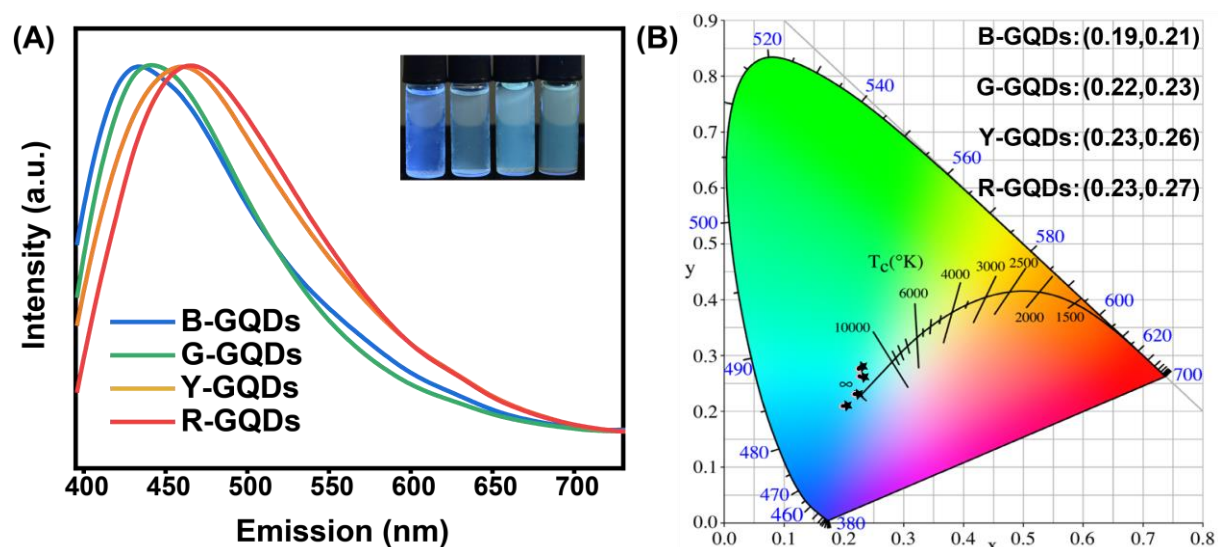

Figure S3. Normalized emission spectra (A) and CIE Coordinates (B) of the four GQDS excited at 375nm in the ethanol phase.

Supporting information 7: Fluorescence decay spectra of the four GQDs in the aqueous phase.
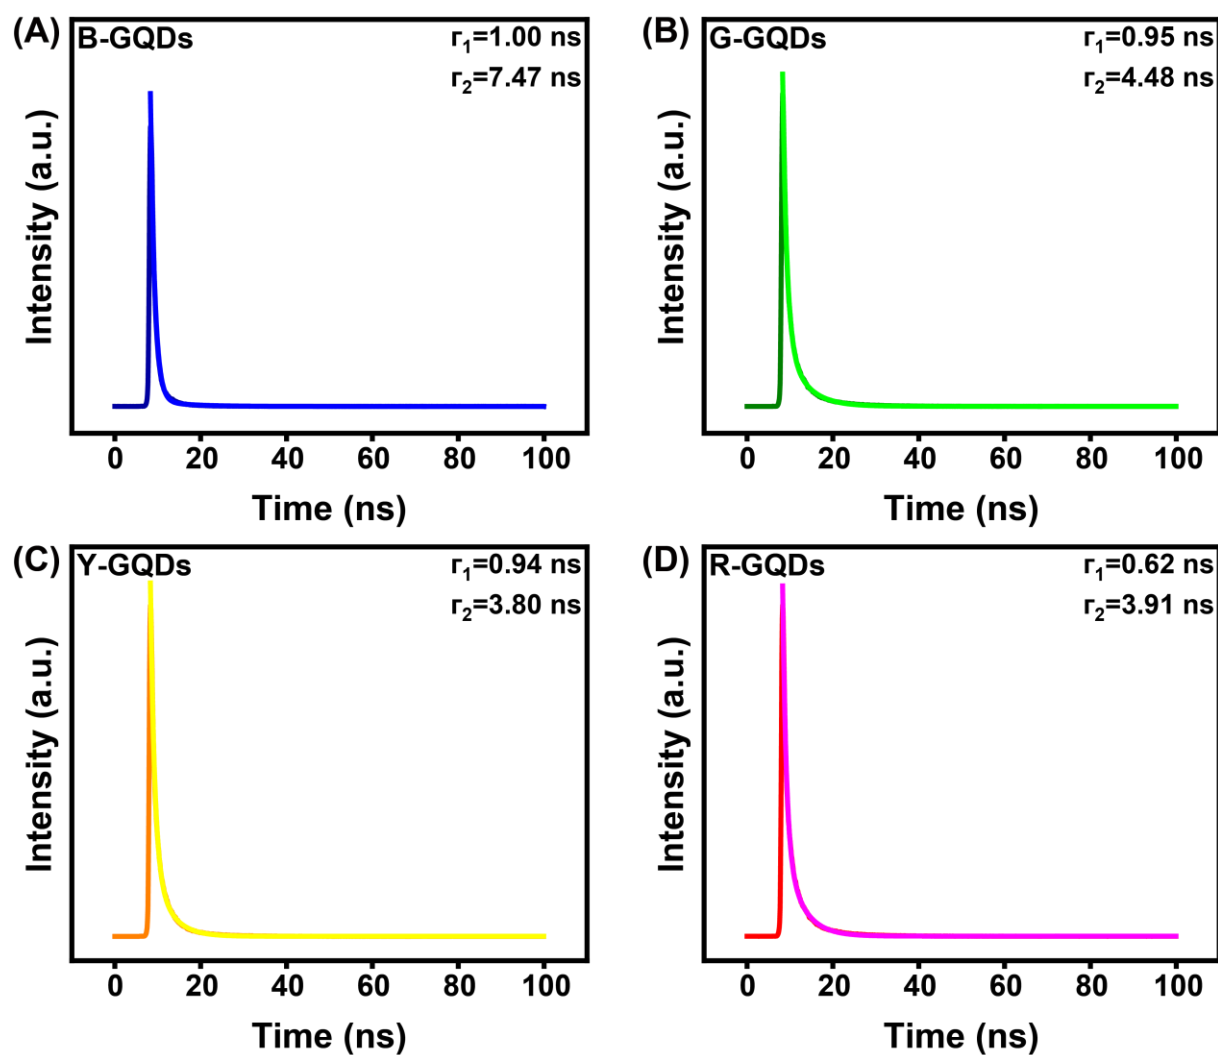

Figure S4. Time-resolved PL decay curves of aqueous solutions of four GQDs at 375 nm excitation.

Supporting information 8: Comparison of the fluorescence lifetimes of the four GQDs dispersions in the aqueous phase.

Table S5. FL attenuation curve fitting parameters of the four GQDs dispersions in the aqueous phase.

Sample	τ_1 (ns)	B_1(%)	τ_2 (ns)	B_2(%)	τ_{avg} (ns)	R^2
B-GQDs	1.00	98.27	7.47	1.73	1.12	0.995
G-GQD	0.95	80.64	4.48	19.36	1.63	0.998
Y-GQD	0.94	79.12	3.80	20.88	1.54	0.998
R-GQD	0.83	76.30	3.96	23.70	1.57	0.998

Supporting information 9：Absolute quantum yield of the four GQDs in the ethanol phase.

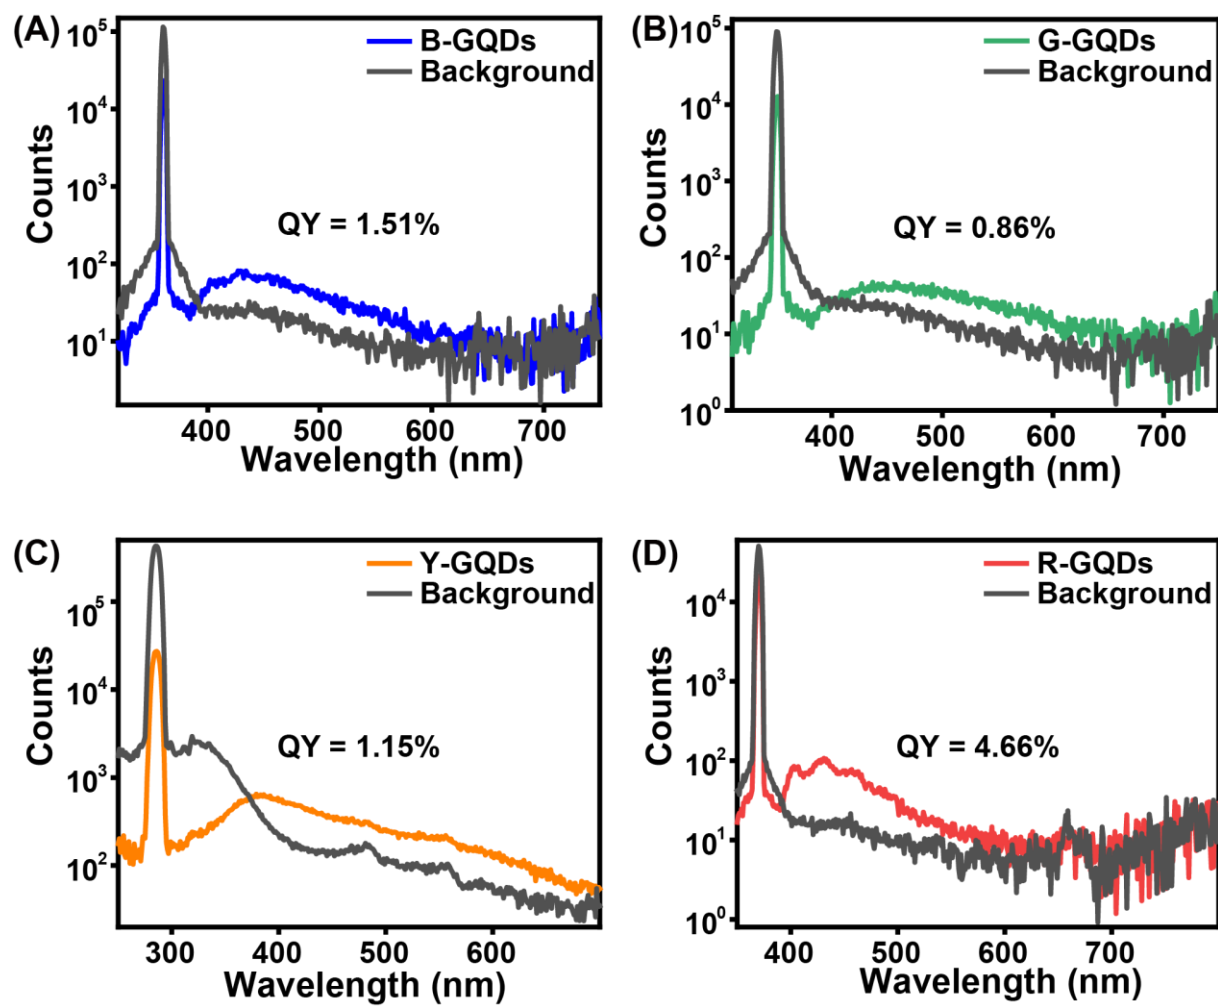

Figure S5. The absolute quantum yield of B-, G-, Y-, R- GQDs in ethanol phase.

Supporting information 10: The band gaps of the four GQDs were calculated from their absorption spectra.

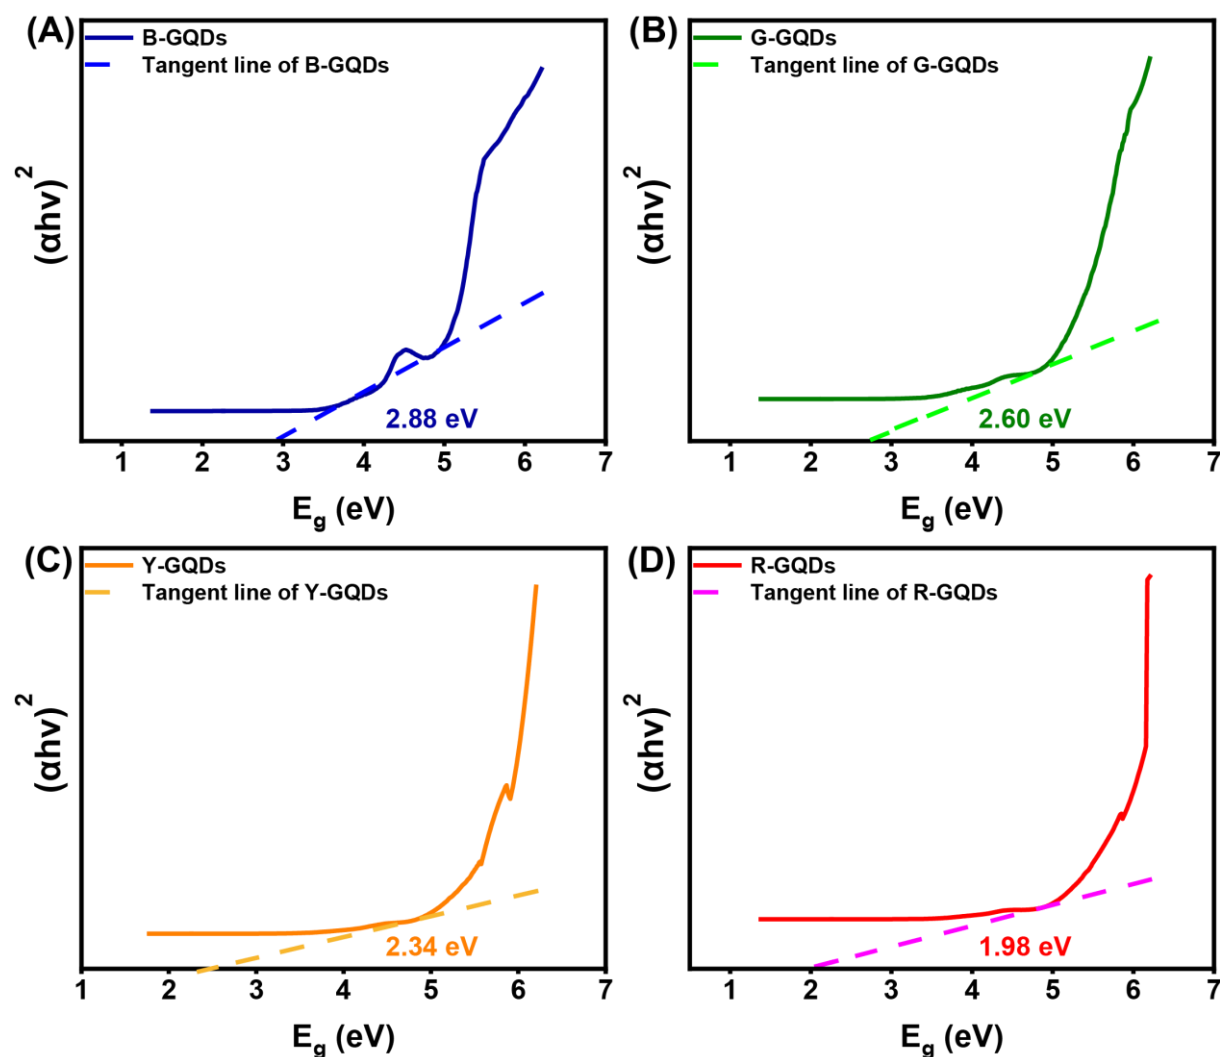

Figure S6. The band gap of B-, G-, Y-, R- GQDs were calculated from their absorption margin.

To confirm the changes in band gap of the four GQDs, UV-vis absorption data were utilized to calculate their optical band gap values using the Tauc relationship (**Figure S6**). The Tauc relationship [9] used in the calculation of the optical band gap is given by the formula

$$(\alpha hv)^n = A (hv - E_g)$$

where α is the absorption coefficient, hv is the photon energy, A is a constant, E_g is the optical band gap, and n is an empirical constant. The absorption value Abs, which is proportional to the absorption coefficient α, is used as the ordinate in the obtained spectrum. Whether Abs or α is employed in the Tauc plot to calculate E_g, the value of E_g remains unaffected. In this study, assuming GQDs as a direct band gap material, the value of n = 1/2 was utilized. Figure S6

12

illustrates the plot of $(\alpha h v)^2$ versus hv for the four GQDs. The optical band gap (E_g) is determined by linear fits of the $(\alpha h v)^2$ and hv curves, considering the intercept of the energy (hv) axis. The estimated optical band gaps from these fits are 2.88 eV, 2.60 eV, 2.34 eV, and 1.98 eV for B-GQDs, G-GQDs, Y-GQDs, and R-GQDs, respectively. These values are consistent with the equation $E_g = 1240/\lambda_g$, which is used to calculate the energy band gap from the emission wavelength. Based on our results, it is confirmed that the increasing size of R-GQDs and the introduction of heteroatoms contribute to a lower band gap compared to B-GQDs.

Supporting information 11: Fluorescence emission spectra of GQDs and CDs.
Figure S7. Comparison of fluorescence emission spectra of GQDs and CDs prepared by a single precursor system.

Supporting information 12: Comparison of the PL properties of GQDs and CDs.

Table S6. Comparison of the PL properties of GQDs and CDs prepared from a single precursor.

Sample	Emission peak (nm)	Sample	Emission peak (nm)
B-GQDs	444	Tyrosine- CDs	415

Supporting information 29: ^{1}H NMR of GQDs during hydrothermal reaction.

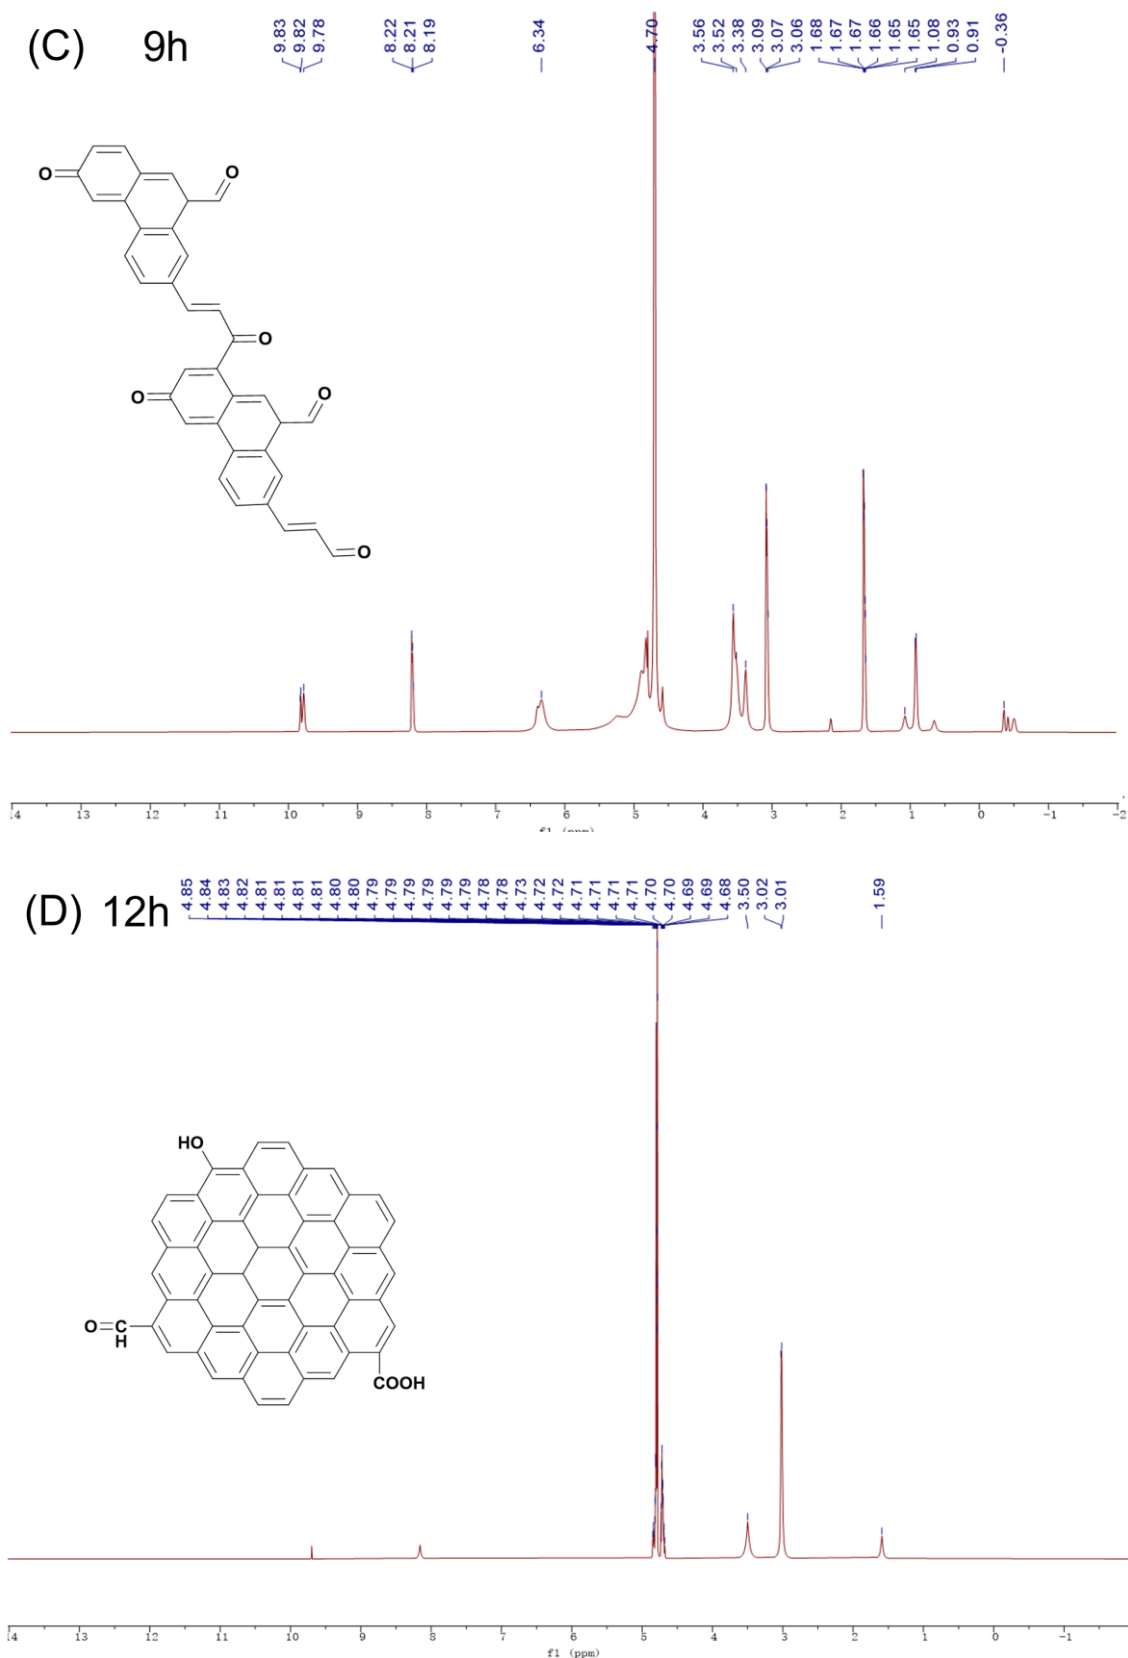

(A)　3h

(B)　6h

25
Figure S15. ^{1}HNMR spectrum (in D_2O) at reaction times of 3h (A), 6h (B), 9h (C), and 12h (D).

The formation mechanism involves a two-step process: First, the cleavage of lignin to produce aromatic compounds, and then the subsequent rearrangement and carbonization leading to the

formation of GQDs. Lignin, an amorphous polymer composed of phenylpropane units, is primarily interconnected through ether bonds or carbon-carbon bonds, with the *β*-O-4 ether bond being the predominant type, comprising approximately 60%-70% of the total bonds. In the first step, NaOH facilitates the cleavage of ether bonds in lignin, resulting in the generation of intermediate lignin fragments, alongside the formation of aromatic monomers bearing phenolic hydroxyl groups. These aromatic monomers serve as molecular precursors for GQD synthesis, leading to the formation of large polycyclic aromatic hydrocarbons through hydrothermal treatment. To gain further insights into the hydrothermal process and the formation mechanism, ^{1}H NMR spectroscopy was employed to study the evolution of the hydrochemical environment, as shown in **Figure S15**. The observed chemical shifts are attributed as follows:

δ = 1-2 ppm: C-H in methoxy group. The peak intensity and diversity increased between 3 and 9 hours, indicating the removal of methyl groups from the lignin structure, resulting in rising and broadening peaks. At 12 hours, the peaks exhibit a weak, narrow singlet state due to carbonization.

δ = 3-4 ppm: C-H in ether bond. The peak intensity reached its highest at 3 hours and lowest at 6-12 hours, indicating a significant cleavage of the ether bond during the reaction.

δ = 4-5 ppm: Aromatic hydrogen on polycyclic aromatic hydrocarbons (PAHs). No significant peak was observed within the first 3 hours. However, a substantial increase was observed at 6 hours, which stabilized at 12 hours. This rise is attributed to changes in the electronic environment within the conjugated regions, caused by the aggregation of aromatic monomers. The high singlets observed at 12 hours indicate a significant change in the chemical positions of hydrogen atoms within the fused aromatic ring.

δ = 6-8 ppm: H on monophenyl ring compounds.

δ = 8-9 ppm: Hydrogen on the phenolic hydroxyl group.

δ = 9-10 ppm: Carbonyl or carboxyl hydrogen.

Hydrogen peaks corresponding to different benzene rings in the lignin monomer appeared within 3 hours. Additionally, Y-GQDs exhibited significant peaks at 8-9 ppm, indicating the presence of hydroxyl groups. After 6 hours of reaction, the hydrogen signal intensity of each benzene ring decreased, while the concentration increased, providing evidence for the polymerization and dehydrogenation of aromatic compounds. Peaks between 9 and 10 ppm suggested the oxidation of hydroxyl groups into carbonyl and carboxyl groups. The peak intensity of benzene in the range of 6-8 ppm gradually decreased at 9 and 12 hours, ultimately reaching the minimum value. This reduction in hydrogen atoms attached to a single benzene

ring is attributed to dehydrogenation, leading to the formation of stable and extensive conjugated regions.

Importantly, the 3-hour spectra exhibited characteristic peaks corresponding to the monomers in the first step, confirming complete lignin cleavage. The 6-hour spectrum showed characteristic peaks associated with the end product of Step 2, while the 9-hour spectrum indicated further reactions of the aforementioned intermediates. Encouragingly, the 12-hour spectra demonstrated characteristic peaks corresponding to molten aromatics with intact conjugated regions. It is noteworthy that due to lignin's inherent heterogeneity, NMR spectroscopy captures different species rather than pure compounds. Consequently, the presence of characteristic peaks corresponding to intermediates at each time interval aids in evaluating the progress and extent of the reaction. In conclusion, the ^{1}H NMR analysis of Y-GQDs at different time points provides valuable insights into the reaction mechanism, confirming the initial decomposition of reactants into monomers followed by a vigorous polymerization and dehydrogenation reaction.
