Experimental detail

Chemicals and reagents

Zn(NO₃)₂·6H₂O, Fe(NO₃)₂·9H₂O, NH₄F and urea were all analytical grade purity from Aladdin Reagent (Shanghai) Co., Ltd. The Ni foam was purchased from Changde Liyuan New Materials Co., Ltd. Reagents were used as received without further purification.

Synthesis of ZnFe₂O₄

In a typical method to synthesize ZnFe₂O₄ spinel nanosheet, 0.297 g Zn(NO₃)₂·6H₂O, 0.808 g Fe(NO₃)₂·9H₂O, 0.296 g NH₄F and 2.88 g urea were dissolved into 160 mL of deionized water under vigorous agitation. Subsequently, the solution was transferred to a 200 mL Teflon-lined stainless-steel autoclave and pre-treated nickel foam (1 cm*1 cm*1.5 mm, 97.2 % porosity) was immersed in solution, which was kept at 140 °C for 4 h. After it was cooled to room temperature, the Ni foam was washed with deionized water and ethanol, and dried at 60 °C overnight. The sample was heated in air at 400 °C for 2 h with a heating rate of 5 °C min⁻¹ to produce ZnFe₂O₄ nanosheets, which was name as ZnFeO-C.

To prepare the samples, an excess amount of NaOH was placed into a mortar and thoroughly ground to a powder. Then, ZnFeO-C was combined with a significant quantity of powdered NaOH, and the NaOH powder was attached to the surface of ZnFeO-C by shaking. Subsequently, the ZnFeO-C with the adhered NaOH powder was transferred to a dielectric barrier discharge plasma reactor. The mixture was then treated in an oxygen atmosphere at 100 V and 2 A for 15 and 30 minutes, resulting in samples named ZnFeO-CP-15 and ZnFeO-CP-30, respectively. In addition, samples with

decreased Zn content (0.148 g $\text{Zn}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$) were also prepared and denoted as ZnFeO-0.25-C and ZnFeO-0.25-CP -15.

Characterization

The crystalline structure analysis were characterized by power X-ray diffraction (XRD) on Rigaku D/M 2500 using a Cu $\text{K}\alpha_1$ source with a scanning rate of $8^\circ \cdot \text{min}^{-1}$. Scanning electron microscope (SEM) and High-resolution transmission electron microscopy (TEM) analysis was carried out using a hitachi SU8100 and Tecnai G2 F20. X-ray photoelectron spectroscopy (XPS) and ultraviolet photoelectron spectroscopy (UPS) were performed by a Thermo-Fisher ESCALAB-250Xi with a monochromatic Al $\text{K}\alpha$ source (1486.6 eV) and He I (21.22 eV), respectively. The adventitious carbon C1s used for XPS element correction is located at 284.8 eV. The UPS spectra were calibrated by the work function of Au (5.1 eV). X-ray absorption near-edge spectra and extended X- Ray absorption fine structure (XANES and EXAFS, Fe K-edge) were performed in transmission mode for the bulk at the Super Photon ring-8 GeV in Harima Science Garden City, Hyogo. The storage ring runs 8 GeV electrons at 99.6 mA constantly during the experiments. The incident beam was monochromated by Si (111) double-crystal monochromators. The XANES and EXAFS data obtained in the experiment were analyzed and fitted with the Athena and Artemis code packages in Demeter [1]. To determine the catalyst loadings and metal content in the electrolyte, Inductively Coupled Plasma Optical Emission Spectrometer (ICPOES) tests were conducted using the Agilent ICPOES 730 instrument. For the ICP characterization, a 1

mL sample was collected at each designated time point (0 s, 1200 s, 2400 s, 3600 s, 7200 s, 14400 s, 25200 s). During the ICP characterization process, 0.5 mL of the electrolyte was directly taken and introduced into the instrument for testing. The instrument provides the direct measurement of the element's concentration in mg/L in the electrolyte.

Electrochemical measurements

The cyclic voltammetry curves (CV), linear sweep voltammograms (LSVs) and electrochemical impedance spectroscopy (EIS, 5 mV amplitude 0.1–100k Hz frequency) tests were performed in a conventional three-electrode system in 1 mol/L KOH with Princeton Applied Research VersaSTAT 3. The electrochemical cell was assembled with the obtained catalyst (The loadings of ZnFeO-C, ZnFeO-CP-15 and ZnFeO-CP-30 were 0.874, 0.710 and 0.522 mg/cm², respectively), Hg|HgO (in 1 mol/L KOH) and a graphite rod as work electrode, reference electrode and counter electrode, respectively. To prepare the RuO₂ electrode, the catalyst (20 mg) was ultrasonically dispersed in a solution containing 3000 μL of ultrapure water (18.2 MΩ·cm), 1000 μL isopropanol and 200 μL of 5% Nafion (Sigma Aldrich, USA). The nickel foam substrate was treated by carefully immersing it, approximately 1 cm deep, into the ink solution using tweezers. The coated foam was then dried, and this process was repeated ten times to achieve a working nickel foam electrode loaded with commercial RuO₂ at a loading of 0.73 mg cm⁻². All the LSV plots were collected at 5 mV·s⁻¹ and then were corrected for the iR compensation. The measured potentials vs. Hg/HgO were converted to a reversible hydrogen electrode (RHE) scale according to the Nernst equation (E_{RHE}

$=E_{\text{Hg/HgO}} + 0.098 + 0.0592 \times \text{pH}$). The electrochemical active surface area (ECSA) was evaluated by the electrochemical double-layered capacitance (C_{dl}) by measuring the capacitive current associated with double-layer charging from the scan-rate dependence of CVs (10, 20, 50, 100 and 200 mV/s) [2]. This non-redox region was selected to a 0.1 V window in the range of 0.927-1.027 V vs. RHE. The C_{dl} can be gained from the linear slope by plotting the different in current density within selected potential against the scan rates. ECSA for all prepared catalysts was calculated by follow equation:

$$\text{ECSA} = \frac{C_{\text{dl,cat}} (\text{mF/cm}^2)}{C_{\text{dl,std}} (\text{mF/cm}^2)}$$

Where the $C_{\text{dl, std}}$ corresponds to the specific capacitance of an atomically smooth material and is approximately equal to 60 $\mu\text{F/cm}^2$ according to previous reports.

DFT calculation

All the calculations were carried out by a plane-wave technique with GGA-PBE to describe the exchange and correlation terms in the Vienna Ab initio Simulation Package (VASP) [3-5]. The projector augmented wave (PAW) pseudo-potential was used to describe the core electrons [6, 7]. All calculations were performed using a cutoff energy of 520 eV with smearing of 0.05 eV. In order to correctly describe the electronic structure of the Fe-3d state, the GGA + U method was used. The U-J value of Fe was selected as 5.3 eV [8]. The vdW corrections were calculated with zero damping DFT-D3 method of Grimme [9, 10]. A G-centered $3 \times 3 \times 3$ and $3 \times 4 \times 1$ k mesh was used in cell and slabs calculations, respectively. The accurate precision of convergence for the geometry optimization were set to 10^{-5} eV for energy change, all atomic structures were fully optimized until the Hellmann–Feynman forces were smaller than 0.05 eV/Å.

Spin polarization and dipole corrections were considered in all calculations. All periodic slabs included 7 layers of atoms and a 15 Å thick vacuum layer, and constrained the bottom layer atoms and relax the top 5 layers of atoms on the surface. In addition, the tetrahedral method and an additional support grid was used in single-point energies calculation.

The (110) plane was chosen as the active surface to study the electronic structure of the catalyst and the electrochemical reaction process because it is considered to be a crucial role in the spinel [11]. The geometric structure models of ZnFeO-C, ZnFeO-CP-15 and ZnFeO-CP-30 (110) planes were shown in Figure S1. The typical adsorbate evolution mechanism (AEM) calculation used the thermodynamic model proposed by Nørskov et al [12]. The lattice oxygen-mediated mechanism (LOM) model referred to the work of Zhu et al [13]. Models of all intermediates of AEM and LOM were shown in Figure S2 and S3. The adsorption energy of intermediate on the catalyst surface could be calculated by the following equations:

$$\Delta E_{\text{ads}}^* = E(\text{ads}^*) - E(*) - E(\text{ads})$$

Where the * represented the active site of the catalyst surface, ads represented the intermediate, and ads* represented the intermediate adsorbed on the active site of the catalyst

The free energy of intermediate adsorption was calculated by the following equations:

$$\Delta G_{\text{ads}} = \Delta E_{\text{ads}} + \Delta E_{\text{ZPE}} + \Delta U_{(0 \rightarrow T)} - T\Delta S [14]$$

Where ΔG_{ads} represented the free energy of intermediate. The $\Delta E_{\text{ZPE}} + \Delta U_{(0 \rightarrow T)} - T\Delta S$ was obtained by VASPKIT processing the result of frequency calculation (Table S7)

[14].

Then the theoretical overpotentials for OER could be calculated using the equations:

$$\eta = \Delta G_{\max} / e - 1.23 \quad (\text{V})$$

In accordance with the computational hydrogen electrode (CHE) model, the chemical potential of H^+ and e^- was related to that of $1/2\text{H}_2$ (g) [12, 15]. Meanwhile, the effects of electrode potential (U) could be treated as an energy shift to free energy change.
